Preface

The *Multithreaded Programming Guide* describes the multithreaded programming interfaces for POSIX and Solaris threads in the Solaris™ Operating Environment. This guide shows application programmers how to create new multithreaded programs and how to add multithreading to existing programs.

Although this guide covers both the POSIX and Solaris threads implementations, most topics assume a POSIX threads interest. Information applying to only Solaris threads is covered in a special chapter.

To understand this guide, a reader must be familiar with

- A UNIX® SVR4 system—preferably the Solaris Operating Environment.
- The C programming language—multithreading is implemented through the libthread library
- The principles of concurrent programming (as opposed to sequential programming)—multithreading requires a different way of thinking about function interactions. Some books you might want to read are:

    - *Algorithms for Mutual Exclusion* by Michel Raynal (MIT Press, 1986)

    - *Concurrent Programming* by Alan Burns & Geoff Davies (Addison-Wesley, 1993)

    - *Distributed Algorithms and Protocols* by Michel Raynal (Wiley, 1988)

    - *Operating System Concepts* by Silberschatz, Peterson, & Galvin (Addison-Wesley, 1991)

    - *Principles of Concurrent Programming* by M. Ben-Ari (Prentice-Hall, 1982)

Ordering Sun Documents

Fatbrain.com, an Internet professional bookstore, stocks select product documentation from Sun Microsystems, Inc.

For a list of documents and how to order them, visit the Sun Documentation Center on Fatbrain.com at `http://www1.fatbrain.com/documentation/sun`.

How This Guide Is Organized

Chapter 1 gives a structural overview of threads implementation in this release.

Chapter 2 discusses the general POSIX threads library routines, emphasizing creating a thread with default attributes.

Chapter 3 covers creating a thread with nondefault attributes.

Chapter 4 covers the threads library synchronization routines.

Chapter 5 discusses changes to the operating environment to support multithreading.

Chapter 6 covers multithreading safety issues.

Chapter 7 covers the basics of compiling and debugging multithreaded applications.

Chapter 8 describes some of the tools available for gathering performance and debugging information about your multithreaded programs.

Chapter 9 covers the Solaris threads (as opposed to POSIX threads) interfaces.

Chapter 10 discusses issues that affect programmers writing multithreaded applications.

Appendix A shows how code can be designed for POSIX threads.

Appendix B shows an example of building a barrier in Solaris threads.

Appendix C lists the safety levels of library routines.

Accessing Sun Documentation Online

The docs.sun.com℠ Web site enables you to access Sun technical documentation online. You can browse the docs.sun.com archive or search for a specific book title or subject. The URL is `http://docs.sun.com`.

What Typographic Conventions Mean

The following table describes the typographic changes used in this book.

TABLE P–1   Typographic Conventions

Typeface or Symbol	Meaning	Example
`AaBbCc123`	The names of commands, files, and directories; on-screen computer output	Edit your `.login` file. Use `ls -a` to list all files. `machine_name% you have mail.`
`AaBbCc123`	What you type, contrasted with on-screen computer output	`machine_name%` **`su`** `Password:`
AaBbCc123	Command-line placeholder: replace with a real name or value	To delete a file, type **`rm`** *filename*.
AaBbCc123	Book titles, new words, or terms, or words to be emphasized.	Read Chapter 6 in *User's Guide*. These are called *class* options. You must be *root* to do this.

Shell Prompts in Command Examples

The following table shows the default system prompt and superuser prompt for the C shell, Bourne shell, and Korn shell.

TABLE P–2   Shell Prompts

Shell	Prompt
C shell prompt	`machine_name%`
C shell superuser prompt	`machine_name#`

TABLE P–2 Shell Prompts *(continued)*

Shell	Prompt
Bourne shell and Korn shell prompt	$
Bourne shell and Korn shell superuser prompt	#

Covering Multithreading Basics

The word *multithreading* can be translated as *multiple threads of control* or *multiple flows of control*. While a traditional UNIX process always has contained and still does contain a single thread of control, multithreading (MT) separates a process into many execution threads, each of which runs independently.

Multithreading your code can

- Improve application responsiveness
- Use multiprocessors more efficiently
- Improve program structure
- Use fewer system resources

This chapter explains some multithreading terms, benefits, and concepts. If you are ready to start using multithreading, skip to Chapter 2.

- "Defining Multithreading Terms" on page 19
- "Meeting Multithreading Standards" on page 21
- "Benefiting From Multithreading" on page 21
- "Understanding Basic Multithreading Concepts" on page 22

Defining Multithreading Terms

Table 1–1 introduces some of the terms used in this book.

TABLE 1–1 Multithreading Terms

Term	Definition
Process	The UNIX environment (such as file descriptors, user ID, and so on) created with the `fork(2)` system call, which is set up to run a program.
Thread	A sequence of instructions executed within the context of a process.
pthreads (POSIX threads)	A POSIX 1003.1c compliant threads interface.
Solaris threads	A Sun Microsystems™ threads interface that is not POSIX compliant. A predecessor of pthreads.
Single-threaded	Restricting access to a single thread.
Multithreaded	Allowing access to two or more threads.
User- or Application-level threads	Threads managed by the threads library routines in user (as opposed to kernel) space.
Lightweight processes	Threads in the kernel that execute kernel code and system calls (also called LWPs).
Bound threads	Threads that are permanently bound to LWPs.
Unbound threads	A default Solaris thread that context switches very quickly without kernel support.
Attribute object	Contains opaque data types and related manipulation functions used to standardize some of the configurable aspects of POSIX threads, mutual exclusion locks (mutexes), and condition variables.
Mutual exclusion locks	Functions that lock and unlock access to shared data.
Condition variables	Functions that block threads until a change of state.
Counting semaphore	A memory-based synchronization mechanism.
Parallelism	A condition that arises when at least two threads are *executing* simultaneously.
Concurrency	A condition that exists when at least two threads are *making progress*. A more generalized form of parallelism that can include time-slicing as a form of virtual parallelism.

Meeting Multithreading Standards

The concept of multithreaded programming goes back to at least the 1960s. Its development on UNIX systems began in the mid-1980s. While there is agreement about what multithreading is and the features necessary to support it, the interfaces used to implement multithreading have varied greatly.

For several years a group called POSIX (Portable Operating System Interface) 1003.4a has been working on standards for multithreaded programming. The standard has now been ratified. This Multithreaded Programming Guide is based on the POSIX standards: P1003.1b final draft 14 (realtime), and P1003.1c final draft 10 (multithreading).

This guide covers both POSIX threads (also called *pthreads*) and Solaris threads. Solaris threads were available in the Solaris 2.4 release, and are not functionally different from POSIX threads. However, because POSIX threads are more portable than Solaris threads, this guide covers multithreading from the POSIX perspective. Subjects specific to Solaris threads only are covered in the Chapter 9.

Benefiting From Multithreading

Improving Application Responsiveness

Any program in which many activities are not dependent upon each other can be redesigned so that each activity is defined as a thread. For example, the user of a multithreaded GUI does not have to wait for one activity to complete before starting another.

Using Multiprocessors Efficiently

Typically, applications that express concurrency requirements with threads need not take into account the number of available processors. The performance of the application improves transparently with additional processors.

Numerical algorithms and applications with a high degree of parallelism, such as matrix multiplications, can run much faster when implemented with threads on a multiprocessor.

Improving Program Structure

Many programs are more efficiently structured as multiple independent or semi-independent units of execution instead of as a single, monolithic thread. Multithreaded programs can be more adaptive to variations in user demands than single-threaded programs.

Using Fewer System Resources

Programs that use two or more processes that access common data through shared memory are applying more than one thread of control.

However, each process has a full address space and operating environment state. The cost of creating and maintaining this large amount of state information makes each process much more expensive than a thread in both time and space.

In addition, the inherent separation between processes can require a major effort by the programmer to communicate between the threads in different processes, or to synchronize their actions.

Combining Threads and RPC

By combining threads and a remote procedure call (RPC) package, you can exploit nonshared-memory multiprocessors (such as a collection of workstations). This combination distributes your application relatively easily and treats the collection of workstations as a multiprocessor.

For example, one thread might create child threads. Each of these children could then place a remote procedure call, invoking a procedure on another workstation. Although the original thread has merely created threads that are now running in parallel, this parallelism involves other computers.

Understanding Basic Multithreading Concepts

Concurrency and Parallelism

In a multithreaded process on a single processor, the processor can switch execution resources between threads, resulting in concurrent execution.

In the same multithreaded process in a shared-memory multiprocessor environment, each thread in the process can run on a separate processor at the same time, resulting in parallel execution.

When the process has fewer or as many threads as there are processors, the threads support system in conjunction with the operating environment ensure that each thread runs on a different processor.

For example, in a matrix multiplication that has the same number of threads and processors, each thread (and each processor) computes a row of the result.

Looking at Multithreading Structure

Traditional UNIX already supports the concept of threads—each process contains a single thread, so programming with multiple processes is programming with multiple threads. But a process is also an address space, and creating a process involves creating a new address space.

Creating a thread is much less expensive when compared to creating a new process, because the newly created thread uses the current process address space. The time it takes to switch between threads is much less than the time it takes to switch between processes, partly because switching between threads does not involve switching between address spaces.

Communicating between the threads of one process is simple because the threads share everything—address space, in particular. So, data produced by one thread is immediately available to all the other threads.

The interface to multithreading support is through a subroutine library, `libpthread` for POSIX threads, and `libthread` for Solaris threads. Multithreading provides flexibility by decoupling kernel-level and user-level resources.

User-Level Threads

Threads are the primary programming interface in multithreaded programming. User-level threads[1] are handled in user space and avoid kernel context switching penalties. An application can have hundreds of threads and still not consume many kernel resources. How many kernel resources the application uses is largely determined by the application.

Threads are visible only from within the process, where they share all process resources like address space, open files, and so on. The following state is unique to each thread.

■ Thread ID

---

1. User-level threads are named to distinguish them from kernel-level threads, which are the concern of systems programmers, only. Because this book is for application programmers, kernel-level threads are not discussed.

- Register state (including PC and stack pointer)

- Stack

- Signal mask

- Priority

- Thread-private storage

Because threads share the process instructions and most of the process data, a change in shared data by one thread can be seen by the other threads in the process. When a thread needs to interact with other threads in the same process, it can do so without involving the operating environment.

By default, threads are very lightweight. But, to get more control over a thread (for instance, to control scheduling policy more), the application can bind the thread. When an application binds threads to execution resources, the threads become kernel resources (see "System Scope (Bound Threads)" on page 26 for more information).

To summarize, user-level threads are:

- Inexpensive to create because they do not need to create their own address space. They are bits of virtual memory that are allocated from your address space at run time.

- Fast to synchronize because synchronization is done at the application level, not at the kernel level.

- Easily managed by the threads library; either `libpthread` or `libthread`.

Lightweight Processes

The threads library uses underlying threads of control called *lightweight processes* that are supported by the kernel. You can think of an LWP as a virtual CPU that executes code or system calls.

You usually do not need to concern yourself with LWPs to program with threads. The information here about LWPs is provided as background, so you can understand the differences in scheduling scope, described on "Process Scope (Unbound Threads)" on page 25.

Note - The LWPs in the Solaris 2, Solaris 7, and Solaris 8 operating environments are *not* the same as the LWPs in the SunOS™ 4.0 LWP library, which are not supported in the Solaris 2, Solaris 7, and Solaris 8 operating environments.

Much as the `stdio` library routines such as `fopen()` and `fread()` use the `open()` and `read()` functions, the threads interface uses the LWP interface, and for many of the same reasons.

Lightweight processes (LWPs) bridge the user level and the kernel level. Each process contains one or more LWP, each of which runs one or more user threads.

(See Figure 1–1.) The creation of a thread usually involves just the creation of some user context, but not the creation of an LWP.
Figure 1–1   User-level Threads and Lightweight Processes

Each LWP is a kernel resource in a kernel pool, and is allocated (attached) and de-allocated (detached) to a thread on a per thread basis. This happens as threads are scheduled or created and destroyed.

Scheduling

POSIX specifies three scheduling policies: first-in-first-out (SCHED_FIFO), round-robin (SCHED_RR), and custom (SCHED_OTHER). SCHED_FIFO is a queue-based scheduler with different queues for each priority level. SCHED_RR is like FIFO except that each thread has an execution time quota.

Both SCHED_FIFO and SCHED_RR are POSIX Realtime extensions. SCHED_OTHER is the default scheduling policy.

See "LWPs and Scheduling Classes" on page 150 for information about the SCHED_OTHER policy, and about emulating some properties of the POSIX SCHED_FIFO and SCHED_RR policies.

Two scheduling scopes are available: process scope for unbound threads and system scope for bound threads. Threads with differing scope states can coexist on the same system and even in the same process. In general, the scope sets the range in which the threads scheduling policy is in effect.

Process Scope (Unbound Threads)

Unbound threads are created PTHREAD_SCOPE_PROCESS. These threads are scheduled in user space to attach and detach from available LWPs in the LWP pool.

LWPs are available to threads in this process only; that is threads are scheduled on these LWPs.

In most cases, threads should be PTHREAD_SCOPE_PROCESS. This allows the threads to float among the LWPs, and this improves threads performance (and is equivalent to creating a Solaris thread in the THR_UNBOUND state). The threads library decides, with regard to other threads, which threads get serviced by the kernel.

System Scope (Bound Threads)

Bound threads are created PTHREAD_SCOPE_SYSTEM. A boundthread is permanently attached to an LWP.

Each bound thread is bound to an LWP for the lifetime of the thread. This is equivalent to creating a Solaris thread in the THR_BOUND state. You can bind a thread to give it an alternate signal stack or to use special scheduling attributes with Realtime scheduling. All scheduling is done by the operating environment.

Note - In neither case, bound or unbound, can a thread be directly accessed by or moved to another process.

Cancellation

Thread cancellation allows a thread to terminate the execution of any other thread in the process. The target thread (the one being cancelled) can keep cancellation requests pending and can perform application-specific cleanup when it acts upon the cancellation notice.

The pthreads cancellation feature permits either asynchronous or deferred termination of a thread. Asynchronous cancellation can occur at any time; deferred cancellation can occur only at defined points. Deferred cancellation is the default type.

Synchronization

Synchronization allows you to control program flow and access to shared data for concurrently executing threads.

The four synchronization models are mutex locks, read/write locks, condition variables, and semaphores.

- Mutex locks allow only one thread at a time to execute a specific section of code, or to access specific data.

- Read/write locks permit concurrent reads and exclusive writes to a protected shared resource. To modify a resource, a thread must first acquire the exclusive write lock. An exclusive write lock is not permitted until all read locks have been released.

- Condition variables block threads until a particular condition is true.

- Counting semaphores typically coordinate access to resources. The count is the limit on how many threads can have access to a semaphore. When the count is reached, the semaphore blocks.

Using the 64–bit Architecture

For application developers, the major difference between the Solaris 64–bit and 32–bit operating environments is the C–language data type model used. The 64–bit data type uses the LP64 model where `longs` and pointers are 64–bits wide. All other fundamental data types remain the same as the in the 32–bit implementation. The 32–bit data type uses the ILP32 model where `ints`, `longs`, and pointers are 32–bits.

The following summary briefly describes the major features and considerations for using the 64–bit environment:

- Large Virtual Address Space

  In the 64-bit environment, a process can have up to 64 bits of virtual address space, or 18 exabytes. This is 4 billion times the current 4 Gbyte maximum of a 32-bit process. Because of hardware restrictions, however, some platforms might not support the full 64 bits of address space.

  Large address space increases the number of threads that can be created with the default stack size (1 Mbyte on 32 bits, 2 Mbytes on 64 bits). The number of threads with the default stack size is approximately 2000 threads on a 32–bit system and 8000 billion on a 64–bit system.

- Kernel Memory Readers

  Because the kernel is an LP64 object that uses 64-bit data structures internally, existing 32-bit applications that use `libkvm`, `/dev/mem`, or `/dev/kmem` do not work properly and must be converted to 64-bit programs.

- `/proc` Restrictions

  A 32-bit program that uses `/proc` is able to look at 32-bit processes, but is unable to understand a 64-bit process; the existing interfaces and data structures that describe the process are not large enough to contain the 64-bit quantities involved. Such programs must be recompiled as 64-bit programs to work for both 32-bit and 64-bit processes.

- 64–bit Libraries

32–bit applications are required to link with 32–bit libraries, and 64–bit applications are required to link with 64–bit libraries. With the exception of those libraries that have become obsolete, all of the system libraries are provided in both 32–bit and 64–bit versions. However, no 64–libraries are provided in static form.

- 64–bit Arithmetic

  Though 64–bit arithmetic has long been available in previous 32–bit Solaris releases, the 64–bit implementation now provides full 64–bit machine registers for integer operations and parameter passing.

- Large Files

  If an application requires only large file support, then it can remain 32-bit and use the Large Files interface. It is, however, recommended that the application be converted to 64-bit to take full advantage of 64-bit capabilities.

Basic Threads Programming

The Threads Library

This chapter introduces the basic threads programming routines from the POSIX threads library, `libpthread(3T)`. This chapter covers *default threads*, or threads with default attribute values, which are the kind of threads that are most often used in multithreaded programming.

Chapter 3, Thread Create Attributes, explains how to create and use threads with nondefault attributes.

Note - Attributes are specified only at thread creation time; they cannot be altered when the thread is being used.

The POSIX (libpthread) routines introduced here have programming interfaces that are similar to the original (`libthread`) Solaris multithreading library.

The following brief roadmap directs you to the discussion of a particular task and its associated man page.

- "Create a Default Thread" on page 30
- "Wait for Thread Termination" on page 31
- "Detaching a Thread" on page 34
- "Create a Key for Thread-Specific Data" on page 35
- "Delete the Thread-Specific Data Key" on page 36
- "Set the Thread-Specific Data Key" on page 37
- "Get the Thread-Specific Data Key" on page 37
- "Get the Thread Identifier" on page 40

Create a Default Thread

When an attribute object is not specified, it is NULL, and the default thread is created with the following attributes:

■ Unbound

■ Nondetached

■ With a default stack and stack size

■ With the parent's priority

You can also create a default attribute object with pthread_attr_init(), and then use this attribute object to create a default thread. See the section "Initialize Attributes" on page 55 for details.

pthread_create(3T)

Use pthread_create(3T) to add a new thread of control to the current process.

```
Prototype:
int pthread_create(pthread_t *tid, const pthread_attr_t *tattr,
    void*(*start_routine)(void *), void *arg);
```

```
#include <pthread.h>
```

```
pthread_attr_t ( )tattr;
pthread_t tid;
extern void *start_routine(void *arg);
void *arg;
int ret;

/* default behavior*/
ret = pthread_create(&tid, NULL, start_routine, arg);

/* initialized with default attributes */
ret = pthread_attr_init(&tattr);
/* default behavior specified*/
ret = pthread_create(&tid, &tattr, start_routine, arg);
```

The `pthread_create()` function is called with *attr* having the necessary state behavior. *start_routine* is the function with which the new thread begins execution. When *start_routine* returns, the thread exits with the exit status set to the value returned by *start_routine* (see "pthread_create(3T)" on page 30).

When `pthread_create()` is successful, the ID of the thread created is stored in the location referred to as *tid*.

Creating a thread using a NULL attribute argument has the same effect as using a default attribute; both create a default thread. When *tattr* is initialized, it acquires the default behavior.

Return Values

`pthread_create()` returns a zero and exits when it completes successfully. Any other returned value indicates that an error occurred. When any of the following conditions are detected, `pthread_create()` fails and returns the corresponding value.

EAGAIN

   A system limit is exceeded, such as when too many LWPs have been created.

EINVAL

   The value of *tattr* is invalid.

Wait for Thread Termination

pthread_join(3T)

Use `pthread_join`(3T) to wait for a thread to terminate.

```
Prototype:
int pthread_join(thread_t tid, void **status);
```

```
#include <pthread.h>

pthread_t tid;
int ret;
int status;

/* waiting to join thread "tid" with status */
ret = pthread_join(tid, &status);

/* waiting to join thread "tid" without status */
ret = pthread_join(tid, NULL);
```

The pthread_join() function blocks the calling thread until the specified thread terminates.

The specified thread must be in the current process and must not be detached. For information on thread detachment, see "Set Detach State" on page 57.

When *status* is not NULL, it points to a location that is set to the exit status of the terminated thread when pthread_join() returns successfully.

Multiple threads cannot wait for the same thread to terminate. If they try to, one thread returns successfully and the others fail with an error of ESRCH.

After pthread_join() returns, any stack storage associated with the thread can be reclaimed by the application.

Return Values

Returns a zero when it completes successfully. Any other returned value indicates that an error occurred. When any of the following conditions are detected, pthread_join() fails and returns the corresponding value.

ESRCH

   tid is not a valid, undetached thread in the current process.

EDEADLK

   tid specifies the calling thread.

EINVAL

   The value of *tid* is invalid.

The pthread_join() routine takes two arguments, giving you some flexibility in its use. When you want the caller to wait until a specific thread terminates, supply that thread's ID as the first argument.

If you are interested in the exit code of the defunct thread, supply the address of an area to receive it.

Remember that pthread_join() works only for target threads that are nondetached. When there is no reason to synchronize with the termination of a particular thread, then that thread should be detached.

Think of a detached thread as being the thread you use in most instances and reserve nondetached threads for only those situations that require them.

A Simple Threads Example

In Code Example 2–1, one thread executes the procedure at the top, creating a helper thread that executes the procedure fetch(), which involves a complicated database lookup and might take some time.

The main thread wants the results of the lookup but has other work to do in the meantime. So it does those other things and then waits for its helper to complete its job by executing pthread_join().

An argument, *pbe*, to the new thread is passed as a stack parameter. This can be done here because the main thread waits for the spun-off thread to terminate. In general, though, it is better to use malloc(3C) to allocate storage from the heap instead of passing an address to thread stack storage, because this address might disappear or be reassigned if the thread terminated.

CODE EXAMPLE 2–1   A Simple Threads Program

```
void mainline (...)
{
        struct phonebookentry *pbe;
        pthread_attr_t tattr;
        pthread_t helper;
        int status;

        pthread_create(&helper, NULL, fetch, &pbe);

            /* do something else for a while */

        pthread_join(helper, &status);
        /* it's now safe to use result */
}

void fetch(struct phonebookentry *arg)
{
        struct phonebookentry *npbe;
        /* fetch value from a database */

        npbe = search (prog_name)
            if (npbe != NULL)
                *arg = *npbe;
        pthread_exit(0);
}

struct phonebookentry {
        char name[64];
```

```
        char phonenumber[32];
        char flags[16];
}
```

Detaching a Thread

pthread_detach(3T)

`pthread_detach`(3T) is an alternative to `pthread_join(3T)()` to reclaim
storage for a thread that is created with a *detachstate* attribute set to
`PTHREAD_CREATE_JOINABLE`.

```
Prototype:
int pthread_detach(thread_t tid);

#include <pthread.h>

pthread_t tid;
int ret;

/* detach thread tid */
ret = pthread_detach(tid);
```

The `pthread_detach()` function is used to indicate to the implementation that
storage for the thread *tid* can be reclaimed when the thread terminates. If *tid* has not
terminated, `pthread_detach()` does not cause it to terminate. The effect of
multiple `pthread_detach()` calls on the same target thread is unspecified.

Return Values

`pthread_detach()` returns a zero when it completes successfully. Any other
returned value indicates that an error occurred. When any of the following conditions
is detected, `pthread_detach()` fails and returns the corresponding value.

`EINVAL`

  tid is not a valid thread.

`ESRCH`

  tid is not a valid, undetached thread in the current process.

Create a Key for Thread-Specific Data

Single-threaded C programs have two basic classes of data—local data and global data. For multithreaded C programs a third class is added—*thread-specific data* (TSD). This is very much like global data, except that it is private to a thread.

Thread-specific data is maintained on a per-thread basis. TSD is the only way to define and refer to data that is private to a thread. Each thread-specific data item is associated with a *key* that is global to all threads in the process. Using the *key*, a thread can access a pointer (*void* *) that is maintained per-thread.

pthread_key_create(3T)

Use `pthread_key_create`(3T) to allocate a *key* that is used to identify thread-specific data in a process. The *key* is global to all threads in the process, and all threads initially have the value `NULL` associated with the key when it is created.

`pthread_key_create()` is called once for each *key* before the *key* is used. There is no implicit synchronization.

Once a *key* has been created, each thread can bind a value to the *key*. The values are specific to the thread and are maintained for each thread independently. The per-thread binding is deallocated when a thread terminates if the *key* was created with a `destructor` function.

```
Prototype:
int pthread_key_create(pthread_key_t *key,
    void (*destructor) (void *));

#include <pthread.h>

pthread_key_t key;
int ret;

/* key create without destructor */
ret = pthread_key_create(&key, NULL);

/* key create with destructor */
ret = pthread_key_create(&key, destructor);
```

When `pthread_key_create()` returns successfully, the allocated key is stored in the location pointed to by *key*. The caller must ensure that the storage and access to this key are properly synchronized.

An optional destructor function, `destructor`, can be used to free stale storage. When a key has a non-`NULL` `destructor` function and the thread has a non-`NULL` value associated with that key, the `destructor` function is called with the current associated value when the thread exits. The order in which the `destructor` functions are called is unspecified.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occur, `pthread_keycreate()` fails and returns the corresponding value.

EAGAIN

   The *key* name space is exhausted.

ENOMEM

   Not enough virtual memory is available in this process to create a new key.

Delete the Thread-Specific Data Key

pthread_key_delete(3T)

Use `pthread_key_delete`(3T) to destroy an existing thread-specific data key. Any memory associated with the key can be freed because the key has been invalidated and will return an error if ever referenced. There is no comparable function in Solaris threads.

```
Prototype:
int pthread_key_delete(pthread_key_t key);

#include <pthread.h>

pthread_key_t key;
int ret;

/* key previously created */
ret = pthread_key_delete(key);
```

Once a *key* has been deleted, any reference to it with the `pthread_setspecific()` or `pthread_getspecific()` call results in the `EINVAL` error.

It is the responsibility of the programmer to free any thread-specific resources before calling the delete function. This function does not invoke any of the destructors.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, `pthread_key_create()` fails and returns the corresponding value.

EINVAL

The *key* value is invalid.

Set the Thread-Specific Data Key

pthread_setspecific(3T)

Use `pthread_setspecific`(3T) to set the thread-specific binding to the specified thread-specific data key.

```
Prototype:
int pthread_setspecific(pthread_key_t key, const void *value);

#include <pthread.h>

pthread_key_t key;
void *value;
int ret;

/* key previously created */
ret = pthread_setspecific(key, value);
```

Return Values

`pthread_setspecific()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occur, `pthread_setspecific()` fails and returns the corresponding value.

```
ENOMEM
```

Not enough virtual memory is available.

```
EINVAL
```

key is invalid.

Note - `pthread_setspecific()` does not free its storage. If a new binding is set, the existing binding must be freed; otherwise, a memory leak can occur..

Get the Thread-Specific Data Key

pthread_getspecific(3T)

Use `pthread_getspecific`(3T) to get the calling thread's binding for *key*, and store it in the location pointed to by *value*.

```
Prototype:
int pthread_getspecific(pthread_key_t key);

#include <pthread.h>

pthread_key_t key;
void *value;

/* key previously created */
value = pthread_getspecific(key);
```

Return Values

No errors are returned.

Global and Private Thread-Specific Data Example

Code Example 2–2 shows an excerpt from a multithreaded program. This code is executed by any number of threads, but it has references to two global variables, *errno* and *mywindow*, that really should be references to items private to each thread.

CODE EXAMPLE 2–2   Thread-Specific Data—Global but Private

```
body() {
    ...

    while (write(fd, buffer, size) == -1) {
        if (errno != EINTR) {
            fprintf(mywindow, "%s\n", strerror(errno));
            exit(1);
        }
    }

    ...

}
```

References to errno should get the system error code from the routine called by this thread, not by some other thread. So, references to errno by one thread refer to a different storage location than references to errno by other threads.

The *mywindow* variable is intended to refer to a stdio stream connected to a window that is private to the referring thread. So, as with errno, references to *mywindow* by one thread should refer to a different storage location (and, ultimately, a different window) than references to *mywindow* by other threads. The only difference here is that the threads library takes care of errno, but the programmer must somehow make this work for *mywindow*.

The next example shows how the references to *mywindow* work. The preprocessor converts references to *mywindow* into invocations of the _mywindow() procedure.

This routine in turn invokes `pthread_getspecific()`, passing it the *mywindow_key* global variable (it really is a global variable) and an output parameter, *win*, that receives the identity of this thread's window.

CODE EXAMPLE 2–3   Turning Global References Into Private References

```
thread_key_t mywin_key;

FILE *_mywindow(void) {
    FILE *win;

    pthread_getspecific(mywin_key, &win);
    return(win);
}

#define mywindow _mywindow()

void routine_uses_win( FILE *win) {
    ...
}

void thread_start(...) {
    ...
    make_mywin();
    ...
    routine_uses_win( mywindow )
    ...
}
```

The *mywin_key* variable identifies a class of variables for which each thread has its own private copy; that is, these variables are thread-specific data. Each thread calls `make_mywin()` to initialize its window and to arrange for its instance of *mywindow* to refer to it.

Once this routine is called, the thread can safely refer to *mywindow* and, after `_mywindow()`, the thread gets the reference to its private window. So, references to *mywindow* behave as if they were direct references to data private to the thread.

Code Example 2–4 shows how to set this up.

CODE EXAMPLE 2–4   Initializing the Thread-Specific Data

```
void make_mywindow(void) {
    FILE **win;
    static pthread_once_t mykeycreated = PTHREAD_ONCE_INIT;

    pthread_once(&mykeycreated, mykeycreate);

    win = malloc(sizeof(*win));
    create_window(win, ...);

    pthread_setspecific(mywindow_key, win);

}

void mykeycreate(void) {
    pthread_keycreate(&mywindow_key, free_key);
```

Basic Threads Programming **39**

```
}

void free_key(void *win) {
    free(win);
}
```

First, get a unique value for the key, *mywin_key*. This key is used to identify the thread-specific class of data. So, the first thread to call `make_mywin()` eventually calls `pthread_keycreate()`, which assigns to its first argument a unique *key*. The second argument is a `destructor` function that is used to deallocate a thread's instance of this thread-specific data item once the thread terminates.

The next step is to allocate the storage for the caller's instance of this thread-specific data item. Having allocated the storage, a call is made to the `create_window()` routine, which sets up a window for the thread and sets the storage pointed to by *win* to refer to it. Finally, a call is made to `pthread_setspecific()`, which associates the value contained in *win* (that is, the location of the storage containing the reference to the window) with the key.

After this, whenever this thread calls `pthread_getspecific()`, passing the global *key*, it gets the value that was associated with this key by this thread when it called `pthread_setspecific()`.

When a thread terminates, calls are made to the `destructor` functions that were set up in `pthread_key_create()`. Each `destructor` function is called only if the terminating thread established a value for the *key* by calling `pthread_setspecific()`.

Get the Thread Identifier

pthread_self(3T)

Use `pthread_self`(3T) to get the ID of the calling thread.

```
Prototype:
pthread_t  pthread_self(void);

#include <pthread.h>

pthread_t tid;

tid = pthread_self();
```

Return Values

Returns the ID of the calling thread.

Compare Thread IDs

pthread_equal(3T)

Use `pthread_equal`(3T) to compare the thread identification numbers of two threads.

```
Prototype:
int  pthread_equal(pthread_t tid1, pthread_t tid2);
```

```
#include <pthread.h>

pthread_t tid1, tid2;
int ret;

ret = pthread_equal(tid1, tid2);
```

Return Values

Returns a nonzero value when *tid1* and *tid2* are equal; otherwise, `zero` is returned. When either *tid1* or *tid2* is an invalid thread identification number, the result is unpredictable.

Initializing Threads

pthread_once(3T)

Use `pthread_once`(3T) to call an initialization routine the first time `pthread_once(3T)` is called. Subsequent calls to `pthread_once()` have no effect.

```
Prototype:
int  pthread_once(pthread_once_t *once_control,
    void (*init_routine)(void));
```

```
#include <pthread.h>

pthread_once_t once_control = PTHREAD_ONCE_INIT;
int ret;

ret = pthread_once(&once_control, init_routine);
```

The *once_control* parameter determines whether the associated initialization routine has been called.

Return Values

pthread_once() returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, pthread_once() fails and returns the corresponding value.

EINVAL

   once_control or *init_routine* is NULL.

Yield Thread Execution

sched_yield(3R)

Use sched_yield(3R) to cause the current thread to yield its execution in favor of another thread with the same or greater priority.

```
Prototype:
int   sched_yield(void);
```

```
#include <sched.h>
```

int *ret;

ret = sched_yield();

Return Values

Returns zero after completing successfully. Otherwise -1 is returned and *errno* is set to indicate the error condition.

ENOSYS

   sched_yield(3R) is not supported in this implementation.

Set the Thread Priority

pthread_setschedparam(3T)

Use pthread_setschedparam(3T) to modify the priority of an existing thread. This function has no effect on scheduling policy.

```
Prototype:
int   pthread_setschedparam(pthread_t tid, int policy,
     const struct sched_param *param);
```

```
#include <pthread.h>

pthread_t tid;
int ret;
struct sched_param param;
int priority;

/* sched_priority will be the priority of the thread */
sched_param.sched_priority = priority;

/* only supported policy, others will result in ENOTSUP */
policy = SCHED_OTHER;

/* scheduling parameters of target thread */
ret = pthread_setschedparam(tid, policy, &param);
```

Return Values

`pthread_setschedparam()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When either of the following conditions occurs, the `pthread_setschedparam()` function fails and returns the corresponding value.

`EINVAL`

The value of the attribute being set is not valid.

`ENOTSUP`

An attempt was made to set the attribute to an unsupported value.

Get the Thread Priority

pthread_getschedparam(3T)

`pthread_getschedparam`(3T) gets the priority of the existing thread.

```
Prototype:
int  pthread_getschedparam(pthread_t tid, int policy,
    struct schedparam *param);

#include <pthread.h>

pthread_t tid;
sched_param param;
int priority;
int policy;
int ret;

/* scheduling parameters of target thread */
ret = pthread_getschedparam (tid, &policy, &param);
```

```
/* sched_priority contains the priority of the thread */
priority = param.sched_priority;
```

Return Values

pthread_getschedparam() returns zero after completing successfully. Any other
returned value indicates that an error occurred. When the following condition occurs,
the function fails and returns the corresponding value.

ESRCH

   The value specified by *tid* does not refer to an existing thread.

Send a Signal to a Thread

pthread_kill(3T)

Use pthread_kill(3T) to send a signal to a thread.

```
Prototype:
int  pthread_kill(thread_t tid, int sig);

#include <pthread.h>
#include <signal.h>

int sig;
pthread_t tid;
int ret;

ret = pthread_kill(tid, sig);
```

pthread_kill() sends the signal *sig* to the thread specified by *tid*. *tid* must be a
thread within the same process as the calling thread. The *sig* argument must be from
the list given in signal(5).

When *sig* is zero, error checking is performed but no signal is actually sent. This can
be used to check the validity of *tid*.

Return Values

Returns zero after completing successfully. Any other returned value indicates that
an error occurred. When either of the following conditions occurs,
pthread_kill() fails and returns the corresponding value.

EINVAL

sig is not a valid signal number.

ESRCH

tid cannot be found in the current process.

Access the Signal Mask of the Calling Thread

pthread_sigmask(3T)

Use `pthread_sigmask`(3T) to change or examine the signal mask of the calling
thread.

```
Prototype:
int pthread_sigmask(int how, const sigset_t *new, sigset_t *old);

#include <pthread.h>
#include <signal.h>

int ret;
sigset_t old, new;

ret = pthread_sigmask(SIG_SETMASK, &new, &old); /* set new mask */
ret = pthread_sigmask(SIG_BLOCK, &new, &old); /* blocking mask */
ret = pthread_sigmask(SIG_UNBLOCK, &new, &old); /* unblocking */
```

how determines how the signal set is changed. It can have one of the following values:

- `SIG_BLOCK`—Add *new* to the current signal mask, where *new* indicates the set of
  signals to block.

- `SIG_UNBLOCK`—Delete *new* from the current signal mask, where new indicates the
  set of signals to unblock.

- `SIG_SETMASK`—Replace the current signal mask with *new*, where *new* indicates
  the new signal mask.

When the value of *new* is NULL, the value of *how* is not significant and the signal
mask of the thread is unchanged. So, to inquire about currently blocked signals,
assign a NULL value to the *new* argument.

The *old* variable points to the space where the previous signal mask is stored, unless
it is NULL.

Return Values

Returns a zero when it completes successfully. Any other returned value indicates that an error occurred. When the following condition occurs, `pthread_sigmask()` fails and returns the corresponding value.

```
EINVAL
```

The value of *how* is not defined.

Forking Safely

pthread_atfork(3T)

See the discussion about `pthread_atfork`(3T) in "The Solution—pthread_atfork(3T)" on page 146.

```
Prototype:

int pthread_atfork(void (*prepare) (void), void (*parent) (void),
    void (*child) (void) );
```

Terminate a Thread

pthread_exit(3T)

Use `pthread_exit`(3T) to terminate a thread.

```
Prototype:
void  pthread_exit(void *status);

#include <pthread.h>

int status;

pthread_exit(&status); /* exit with status */
```

The `pthread_exit()` function terminates the calling thread. All thread-specific data bindings are released. If the calling thread is not detached, then the thread's ID and the exit status specified by *status* are retained until the thread is waited for (blocked). Otherwise, *status* is ignored and the thread's ID can be reclaimed immediately. For information on thread detachment, see "Set Detach State" on page 57.

Return Values

The calling thread terminates with its exit status set to the contents of *status* if *status* is not `NULL`.

Finishing Up

A thread can terminate its execution in the following ways:

- By returning from its first (outermost) procedure, the threads start routine; see `pthread_create(3T)`

- By calling `pthread_exit()`, supplying an exit status

- By termination with POSIX cancel functions; see `pthread_cancel()`

The default behavior of a thread is to linger until some other thread has acknowledged its demise by "joining" with it. This is the same as the default `pthread_create()` attribute being non-detached; see `pthread_detach(3T)`. The result of the join is that the joining thread picks up the exit status of the dying thread and the dying thread vanishes.

An important special case arises when the initial thread — the one calling `main()`,— returns from calling `main()` or calls `exit(3C)`. This action causes the entire process to be terminated, along with all its threads. So take care to ensure that the initial thread does not return from `main()` prematurely.

Note that when the main thread merely calls `pthread_exit(3T)`, it terminates only itself—the other threads in the process, as well as the process, continue to exist. (The process terminates when all threads terminate.)

Cancellation

The POSIX threads library introduces the ability to cancel threads to threads programming. Cancellation allows a thread to terminate the execution of any other thread, or all threads, in the process. Cancellation is an option when all further operations of a related set of threads are undesirable or unnecessary. A good method is to cancel all threads, restore the process to a consistent state, and then return to the point of origin.

One example of thread cancellation is an asynchronously generated cancel condition, such as, when a user requesting to close or exit some running application. Another example is the completion of a task undertaken by a number of threads. One of the threads might ultimately complete the task while the others continue to operate. Since they are serving no purpose at that point, they all should be cancelled.

There are dangers in performing cancellations. Most deal with properly restoring invariants and freeing shared resources. A thread that is cancelled without care might

leave a mutex in a locked state, leading to a deadlock. Or it might leave a region of memory allocated with no way to identify it and therefore no way to free it.

The `pthreads` library specifies a cancellation interface that permits or forbids cancellation programmatically. The library defines the set of points at which cancellation can occur *(cancellation points)*. It also allows the scope of *cancellation handlers*, which provide clean up services, to be defined so that they are sure to operate when and where intended.

Placement of cancellation points and the effects of cancellation handlers must be based on an understanding of the application. A mutex is explicitly not a cancellation point and should be held only the minimal essential time.

Limit regions of asynchronous cancellation to sequences with no external dependencies that could result in dangling resources or unresolved state conditions. Take care to restore cancellation state when returning from some alternate, nested cancellation state. The interface provides features to facilitate restoration: `pthread_setcancelstate(3T)` preserves the current cancel state in a referenced variable; `pthread_setcanceltype(3T)` preserves the current cancel type in the same way.

Cancellations can occur under three different circumstances:

■ Asynchronously

■ At various points in the execution sequence as defined by the standard

■ At discrete points specified by the application

By default, cancellation can occur only at well-defined points as defined by the POSIX standard.

In all cases, take care that resources and state are restored to a condition consistent with the point of origin.

Cancellation Points

Be careful to cancel a thread only when cancellation is safe. The `pthreads` standard specifies several cancellation points, including:

■ Programmatically establish a thread cancellation point through a `pthread_testcancel(3T)` call.

■ Threads waiting for the occurrence of a particular condition in `pthread_cond_wait(3T)` or `pthread_cond_timedwait(3T)`.

■ Threads waiting for termination of another thread in `pthread_join(3T)`.

■ Threads blocked on `sigwait(2)`.

■ Some standard library calls. In general, these are functions in which threads can block; see the man page `cancellation(3T)` for a list.

Cancellation is enabled by default. At times you might want an application to disable cancellation. This has the result of deferring all cancellation requests until they are enabled again.

See "pthread_setcancelstate(3T)" on page 50 for information about disabling cancellation.

Cancel a Thread

pthread_cancel(3T)

Use `pthread_cancel`(3T) to cancel a thread.

Prototype:

```
int pthread_cancel(pthread_t thread);
```

```
#include <pthread.h>
```

```
pthread_t thread;
int ret;
```

```
ret = pthread_cancel(thread);
```

How the cancellation request is treated depends on the state of the target thread. Two functions, `pthread_setcancelstate(3T)` and `pthread_setcanceltype(3T)`, determine that state.

Return Values

`pthread_cancel()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the function fails and returns the corresponding value.

`ESRCH`

   No thread could be found corresponding to that specified by the given thread ID.

Enable or Disable Cancellation

pthread_setcancelstate(3T)

Use pthread_setcancelstate(3T) to enable or disable thread cancellation. When a thread is created, thread cancellation is enabled by default.

Prototype:

```
int pthread_setcancelstate(int state, int *oldstate);

#include <pthread.h>

int oldstate;
int ret;

/* enabled */
ret = pthread_setcancelstate(PTHREAD_CANCEL_ENABLE, &oldstate);

/* disabled */
ret = pthread_setcancelstate(PTHREAD_CANCEL_DISABLE, &oldstate);
```

Return Values

pthread_setcancelstate() returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the pthread_setcancelstate() function fails and returns the corresponding value.

EINVAL

The state is not PTHREAD_CANCEL_ENABLE or PTHREAD_CANCEL_DISABLE.

Set Cancellation Type

pthread_setcanceltype(3T)

Use pthread_setcanceltype(3T) to set the cancellation type to either deferred or asynchronous mode. When a thread is created, the cancellation type is set to deferred mode by default. In deferred mode, the thread can be cancelled only at cancellation points. In asynchronous mode, a thread can be cancelled at any point during its execution. Using asynchronous mode is discouraged.

Prototype:

```
int pthread_setcanceltype(int type, int *oldtype);
```

```
#include <pthread.h>

int oldtype;
int ret;

/* deferred mode */
ret = pthread_setcanceltype(PTHREAD_CANCEL_DEFERRED, &oldtype);

/* async mode*/
ret = pthread_setcanceltype(PTHREAD_CANCEL_ASYNCHRONOUS, &oldtype);
```

Return Values

`pthread_setcanceltype()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

> The type is not `PTHREAD_CANCEL_DEFERRED` or
> `PTHREAD_CANCEL_ASYNCHRONOUS`.

Create a Cancellation Point

pthread_testcancel(3T)

Use `pthread_testcancel`(3T) to establish a cancellation point for a thread.

Prototype:

```
void pthread_testcancel(void);

#include <pthread.h>

pthread_testcancel();
```

The `pthread_testcancel()` function is effective when thread cancellation is enabled and in deferred mode. Calling this function while cancellation is disabled has no effect.

Be careful to insert `pthread_testcancel()` only in sequences where it is safe to cancel a thread. In addition to programmatically establishing cancellation points through the `pthread_testcancel()` call, the pthreads standard specifies several cancellation points. See "Cancellation Points" on page 48 for more details.

There is no return value.

Push a Handler Onto the Stack

Use cleanup handlers to restore conditions to a state consistent with that at the point of origin, such as cleaning up allocated resources and restoring invariants. Use the `pthread_cleanup_push(3T)` and `pthread_cleanup_pop(3T)` functions to manage the handlers.

Cleanup handlers are pushed and popped in the same lexical scope of a program. They should always match; otherwise compiler errors will be generated.

pthread_cleanup_push(3T)

Use `pthread_cleanup_push(3T)` to push a cleanup handler onto a cleanup stack (LIFO).

Prototype:

```
void pthread_cleanup_push(void(*routine)(void *), void *args);
```

```
#include <pthread.h>

/* push the handler "routine" on cleanup stack */
pthread_cleanup_push (routine, arg);
```

Pull a Handler Off the Stack

pthread_cleanup_pop(3T)

Use `pthread_cleanup_pop(3T)` to pull the cleanup handler off the cleanup stack.

A nonzero argument in the pop function removes the handler from the stack and executes it. An argument of zero pops the handler without executing it.

`pthread_cleanup_pop()` is effectively called with a nonzero argument if a thread either explicitly or implicitly calls pthread_exit(3T) or if the thread accepts a cancel request.

Prototype:
```
void pthread_cleanup_pop(int execute);
```

```
#include <pthread.h>

/* pop the "func" out of cleanup stack and execute "func" */
pthread_cleanup_pop (1);

/* pop the "func" and DONT execute "func" */
pthread_cleanup_pop (0);
```

There are no return values.

Thread Create Attributes

The previous chapter covered the basics of threads creation using default attributes. This chapter discusses setting attributes at thread creation time.

Note that only pthreads uses attributes and cancellation, so the API covered in this chapter is for POSIX threads only. Otherwise, the *functionality* for Solaris threads and `pthreads` is largely the same. (See Chapter 9, Programming With Solaris Threads, for more information about similarities and differences.)

Attributes

Attributes are a way to specify behavior that is different from the default. When a thread is created with `pthread_create(3T)` or when a synchronization variable is initialized, an attribute object can be specified. The defaults are usually sufficient.

Note - Attributes are specified only at thread creation time; they cannot be altered while the thread is being used.

An attribute object is opaque, and cannot be directly modified by assignments. A set of functions is provided to initialize, configure, and destroy each object type.

Once an attribute is initialized and configured, it has process-wide scope. The suggested method for using attributes is to configure all required state specifications at one time in the early stages of program execution. The appropriate attribute object can then be referred to as needed.

Using attribute objects has two primary advantages.

- First, it adds to code portability.

  Even though supported attributes might vary between implementations, you need not modify function calls that create thread entities because the attribute object is hidden from the interface.

  If the target port supports attributes that are not found in the current port, provision must be made to manage the new attributes. This is an easy porting task though, because attribute objects need only be initialized once in a well-defined location.

- Second, state specification in an application is simplified.

  As an example, consider that several sets of threads might exist within a process, each providing a separate service, and each with its own state requirements.

  At some point in the early stages of the application, a thread attribute object can be initialized for each set. All future thread creations will then refer to the attribute object initialized for that type of thread. The initialization phase is simple and localized, and any future modifications can be made quickly and reliably.

Attribute objects require attention at process exit time. When the object is initialized, memory is allocated for it. This memory must be returned to the system. The `pthreads` standard provides function calls to destroy attribute objects.

Initialize Attributes

pthread_attr_init(3T)

Use `pthread_attr_init`(3T) to initialize object attributes to their default values. The storage is allocated by the thread system during execution.

Prototype:

```
int pthread_attr_init(pthread_attr_t *tattr);

#include <pthread.h>

pthread_attr_t tattr;
int ret;

/* initialize an attribute to the default value */
ret = pthread_attr_init(&tattr);
```

Table 3–1 shows the default values for attributes (*tattr*) .

TABLE 3–1   Default Attribute Values for *tattr*

Attribute	Value	Result
scope	PTHREAD_SCOPE_PROCESS	New thread is unbound – not permanently attached to LWP.
detachstate	PTHREAD_CREATE_JOINABLE	Exit status and thread are preserved after the thread terminates.
stackaddr	NULL	New thread has system-allocated stack address.
stacksize	1 megabyte	New thread has system-defined stack size.
priority		New thread inherits parent thread priority.

TABLE 3–1   Default Attribute Values for *tattr*   *(continued)*

Attribute	Value	Result
inheritsched	PTHREAD_INHERIT_SCHED	New thread inherits parent thread scheduling priority.
schedpolicy	SCHED_OTHER	New thread uses Solaris-defined fixed priority scheduling; threads run until preempted by a higher-priority thread or until they block or yield.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

ENOMEM

> Returned when there is not enough memory to initialize the thread attributes object.

Destroy Attributes

pthread_attr_destroy(3T)

Use pthread_attr_destroy(3T) to remove the storage allocated during initialization. The attribute object becomes invalid.

```
Prototype:
int pthread_attr_destroy(pthread_attr_t *tattr);

#include <pthread.h>

pthread_attr_t tattr;
int ret;

/* destroy an attribute */
ret = pthread_attr_destroy(&tattr);
```

Return Values

`pthread_attr_destroy()` returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

Indicates that the value of *tattr* was not valid.

Set Detach State

pthread_attr_setdetachstate(3T)

When a thread is created detached (`PTHREAD_CREATE_DETACHED`), its thread *ID* and other resources can be reused as soon as the thread terminates. Use `pthread_attr_setdetachstate`(3T) when the calling thread does not want to wait for the thread to terminate.

When a thread is created nondetached (`PTHREAD_CREATE_JOINABLE`), it is assumed that you will be waiting for it. That is, it is assumed that you will be executing a `pthread_join(3T)()` on the thread.

Whether a thread is created detached or nondetached, the process does not exit until all threads have exited. See "Finishing Up" on page 47 for a discussion of process termination caused by premature exit from `main()`.

Prototype:

```
int pthread_attr_setdetachstate(pthread_attr_t *tattr,int detachstate);
```

```
#include <pthread.h>

pthread_attr_t tattr;
int ret;

/* set the thread detach state */
ret = pthread_attr_setdetachstate(&tattr,PTHREAD_CREATE_DETACHED);
```

Note - When there is no explicit synchronization to prevent it, a newly created, detached thread can die and have its thread ID reassigned to another new thread before its creator returns from `pthread_create()`.

For nondetached (`PTHREAD_CREATE_JOINABLE`) threads, it is very important that some thread join with it after it terminates—otherwise the resources of that thread

are not released for use by new threads. This commonly results in a memory leak. So when you do not want a thread to be joined, create it as a detached thread.

CODE EXAMPLE 3–1   Creating a Detached Thread

```
#include <pthread.h>

pthread_attr_t tattr;
pthread_t tid;
void *start_routine;
void arg
int ret;

/* initialized with default attributes */
ret = pthread_attr_init()(&tattr);
ret = pthread_attr_setdetachstate()(&tattr,PTHREAD_CREATE_DETACHED);
ret = pthread_create()(&tid, &tattr, start_routine, arg);
```

Return Values

`pthread_attr_setdetachstate()` returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

Indicates that the value of *detachstate* or *tattr* was not valid.

Get Detach State

pthread_attr_getdetachstate(3T)

Use `pthread_attr_getdetachstate`(3T) to retrieve the thread create state, which can be either detached or joined.

Prototype:

```
int pthread_attr_getdetachstate(const pthread_attr_t *tattr,
    int *detachstate;

#include <pthread.h>

pthread_attr_t tattr;
int detachstate;
int ret;

/* get detachstate of thread */
ret = pthread_attr_getdetachstate (&tattr, &detachstate);
```

Return Values

`pthread_attr_getdetachstate()` returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

EINVAL

Indicates that the value of *detachstate* is NULL or *tattr* is invalid.

Set Stack Guard Size

pthread_attr_setguardsize(3T)

`pthread_attr_setguardsize`(3T) sets the *guardsize* of the *attr* object.

The *guardsize* argument provides protection against overflow of the stack pointer. If a thread's stack is created with guard protection, the implementation allocates extra memory at the overflow end of the stack as a buffer against stack overflow of the stack pointer. If an application overflows into this buffer an error results (possibly in a SIGSEGV signal being delivered to the thread).

The guardsize attribute is provided to the application for two reasons:

1. Overflow protection can potentially result in wasted system resources. An application that creates a large number of threads, and knows its threads will never overflow their stack, can save system resources by turning off guard areas.

2. When threads allocate large data structures on stack, a large guard area may be needed to detect stack overflow.

If *guardsize* is zero, a guard area will not be provided for threads created with *attr*. If *guardsize* is greater than zero, a guard area of at least size *guardsize* bytes is provided for each thread created with *attr*. By default, a thread has an implementation-defined, non-zero guard area.

A conforming implementation is permitted to round up the value contained in guardsize to a multiple of the configurable system variable PAGESIZE (see PAGESIZE in `sys/mman.h`). If an implementation rounds up the value of *guardsize* to a multiple of PAGESIZE, a call to `pthread_attr_getguardsize()` specifying *attr* will store, in *guardsize*, the guard size specified in the previous call to `pthread_attr_setguardsize()`.

```
#include <pthread.h>

int pthread_attr_setguardsize(pthread_attr_t *attr, size_t  guardsize);
```

Return Value

`pthread_attr_setguardsize()` fails if:

EINVAL

The argument *attr* is invalid, the argument *guardsize* is invalid, or the argument *guardsize* contains an invalid value.

Get Stack Guard Size

pthread_attr_getguardsize(3T)

`pthread_attr_getguardsize`(3T) gets the *guardsize* of the *attr* object.

A conforming implementation is permitted to round up the value contained in *guardsize* to a multiple of the configurable system variable PAGESIZE (see PAGESIZE in `sys/mman.h`). If an implementation rounds up the value of *guardsize* to a multiple of PAGESIZE, a call to `pthread_attr_getguardsize()` specifying *attr* will store, in *guardsize*, the guard size specified in the previous call to `pthread_attr_setguardsize()`.

```
#include <pthread.h>

int pthread_attr_getguardsize(const pthread_attr_t *attr, size_t  *guardsize);
```

Return Value

`pthread_attr_getguardsize()` fails if:

EINVAL

The argument *attr* is invalid, the argument *guardsize* is invalid, or the argument *guardsize* contains an invalid value,.

Set Scope

pthread_attr_setscope(3T)

Use `pthread_attr_setscope`(3T) to create a bound thread (PTHREAD_SCOPE_SYSTEM) or an unbound thread (PTHREAD_SCOPE_PROCESS).

Note - Both thread types are accessible only within a given process.

Prototype:

```
int pthread_attr_setscope(pthread_attr_t *tattr,int scope);
```

```
#include <pthread.h>

pthread_attr_t tattr;
int ret;

/* bound thread */
ret = pthread_attr_setscope(&tattr, PTHREAD_SCOPE_SYSTEM);

/* unbound thread */
ret = pthread_attr_setscope(&tattr, PTHREAD_SCOPE_PROCESS);
```

Notice that there are three function calls in this example: one to initialize the attributes, one to set any variations from the default attributes, and one to create the pthreads.

```
#include <pthread.h>

pthread_attr_t attr;
pthread_t tid;
void start_routine;
void arg;
int ret;

/* initialized with default attributes */
ret = pthread_attr_init (&tattr);

/* BOUND behavior */
ret =  pthread_attr_setscope(&tattr, PTHREAD_SCOPE_SYSTEM);
ret = pthread_create (&tid, &tattr, start_routine, arg);
```

Return Values

pthread_attr_setscope() returns zero after completing *successfully*. Any other returned value indicates that an error occurred. If the following conditions occur, the function fails and returns the corresponding value.

EINVAL

An attempt was made to set *tattr* to a value that is not valid.

Get Scope

pthread_attr_getscope(3T)

Use pthread_attr_getscope(3T) to retrieve the thread scope, which indicates whether the thread is bound or unbound.

Prototype:

int pthread_attr_getscope(pthread_attr_t *tattr, int *scope);

```
#include <pthread.h>

pthread_attr_t tattr;
int scope;
int ret;

/* get scope of thread */
ret = pthread_attr_getscope(&tattr, &scope);
```

Return Values

pthread_attr_getscope() returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

EINVAL

The value of *scope* is NULL or *tattr* is invalid.

Set Thread Concurrency Level

pthread_setconcurrency(3T)

Unbound threads in a process might or might not be required to be simultaneously active. By default, the threads implementation ensures that a sufficient number of threads are active so that the process can continue to make progress. While this conserves system resources, it might not produce the most effective level of concurrency.

pthread_setconcurrency(3T) allows an application to inform the threads implementation of its desired concurrency level, *new_level.* The actual level of concurrency provided by the implementation as a result of this function call is unspecified. (For Solaris threads, see "thr_setconcurrency(3T)" on page 204.)

If *new_level* is zero, the implementation maintains the concurrency level at its discretion as if pthread_setconcurrency() was never called.

When an application calls pthread_setconcurrency(), it is informing the implementation of its desired concurrency level. The implementation uses this as a hint, not a requirement.

```
#include <pthread.h>

int pthread_setconcurrency(int new_level);
```

Return Value

pthread_setconcurrency() fails if:

```
EINVAL
```

The value specified by *new_level* is negative.

```
EAGAIN
```

The value specified by *new_level* would cause a system resource to be exceeded.

Get Thread Concurrency Level

pthread_getconcurrency(3T)

`pthread_getconcurrency`(3T) returns the value set by a previous call to `pthread_setconcurrency()`. If the `pthread_setconcurrency()` function was not previously called, `pthread_getconcurrency()` returns zero to indicate that the implementation is maintaining the concurrency level. (For Solaris threads, see "thr_getconcurrency(3T)" on page 205.)

```
#include <pthread.h>
```

```
int pthread_getconcurrency(void);
```

Return Value

`pthread_getconcurrency()` always returns the concurrency level set by a previous call to `pthread_setconcurrency()`. If `pthread_setconcurrency()` has never been called, `pthread_getconcurrency()` returns zero.

Set Scheduling Policy

pthread_attr_setschedpolicy(3T)

Use `pthread_attr_setschedpolicy`(3T) to set the scheduling policy. The POSIX draft standard specifies scheduling policy attributes of `SCHED_FIFO` (first-in-first-out), `SCHED_RR` (round-robin), or `SCHED_OTHER` (an implementation-defined method).

- `SCHED_FIFO`

  First-In-First-Out; threads scheduled to this policy, if not preempted by a higher priority, will proceed until completion. Threads whose contention scope is system (`PTHREAD_SCOPE_SYSTEM`) are in real-time (`RT`) scheduling class and the calling process must have an effective user id of `0`. `SCHED_FIFO` for threads that have a

contention scope of process (PTHREAD_SCOPE_PROCESS) is based on the TS scheduling class.

- SCHED_RR

  Round-Robin; threads scheduled to this policy, if not preempted by a higher priority, will execute for a time period determined by the system. Threads whosethat have a contention scope of system (PTHREAD_SCOPE_SYSTEM) are in real-time (RT) scheduling class and the calling process must have an effective user id of 0. SCHED_RR for threads that have a contention scope of process (PTHREAD_SCOPE_PROCESS) is based on the TS scheduling class.

SCHED_FIFO and SCHED_RR are optional in POSIX, and are supported for real time bound threads only.

Currently, only the Solaris SCHED_OTHER, time-sharing, default value is supported in pthreads. For a discussion of scheduling, see the section "Scheduling" on page 25.

Prototype:

```
int pthread_attr_setschedpolicy(pthread_attr_t *tattr, int policy);

#include <pthread.h>

pthread_attr_t tattr;
int policy;
int ret;

/* set the scheduling policy to SCHED_OTHER */
ret = pthread_attr_setschedpolicy(&tattr, SCHED_OTHER);
```

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. When either of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

An attempt was made to set *tattr* to a value that is not valid.

ENOTSUP

An attempt was made to set the attribute to an unsupported value.

Get Scheduling Policy

pthread_attr_getschedpolicy(3T)

Use `pthread_attr_getschedpolicy`(3T) to retrieve the scheduling policy.
Currently, only the Solaris-based `SCHED_OTHER` default value is supported in
pthreads.

Prototype:

```
int pthread_attr_getschedpolicy(pthread_attr_t *tattr, int *policy);

#include <pthread.h>

pthread_attr_t tattr;
int policy;
int ret;

/* get scheduling policy of thread */
ret = pthread_attr_getschedpolicy (&tattr, &policy);
```

Return Values

Returns zero after completing successfully. Any other returned value indicates that
an error occurred. If the following condition occurs, the function fails and returns the
corresponding value.

`EINVAL`

> The parameter *policy* is `NULL` or *tattr* is invalid.

Set Inherited Scheduling Policy

pthread_attr_setinheritsched(3T)

Use `pthread_attr_setinheritsched`(3T) to set the inherited scheduling policy.

An *inherit* value of `PTHREAD_INHERIT_SCHED` (the default) means that the
scheduling policies defined in the creating thread are to be used, and any scheduling
attributes defined in the `pthread_create()` call are to be ignored. If
`PTHREAD_EXPLICIT_SCHED` is used, the attributes from the `pthread_create()`
call are to be used.

Prototype:

```
int pthread_attr_setinheritsched(pthread_attr_t *tattr, int inherit);
```

```
#include <pthread.h>

pthread_attr_t tattr;
int inherit;
int ret;

/* use the current scheduling policy */
ret = pthread_attr_setinheritsched(&tattr, PTHREAD_EXPLICIT_SCHED);
```

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. When either of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

    An attempt was made to set *tattr* to a value that is not valid.

ENOTSUP

    An attempt was made to set the attribute to an unsupported value.

Get Inherited Scheduling Policy

pthread_attr_getinheritsched(3T)

 pthread_attr_getinheritsched(3T) returns the scheduling policy set by pthread_attr_setinheritsched().

Prototype:

```
int pthread_attr_getinheritsched(pthread_attr_t *tattr, int *inherit);

#include <pthread.h>

pthread_attr_t tattr;
int inherit;
int ret;

/* get scheduling policy and priority of the creating thread */
ret = pthread_attr_getinheritsched (&tattr, &inherit);
```

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

```
EINVAL
```

The parameter *inherit* is `NULL` or *tattr* is invalid.

Set Scheduling Parameters

pthread_attr_setschedparam(3T)

`pthread_attr_setschedparam`(3T) sets the scheduling parameters.

Scheduling parameters are defined in the `param` structure; only priority is supported. Newly created threads run with this priority.

- `SCHED_FIFO`

  First-In-First-Out; threads scheduled to this policy, if not preempted by a higher priority, will proceed until completion. Threads that have a contention scope of system (`PTHREAD_SCOPE_SYSTEM`) are in real-time (`RT`) scheduling class and the calling process must have an effective user id of `0`. `SCHED_FIFO` for threads that have a contention scope of process (`PTHREAD_SCOPE_PROCESS`) is based on the `TS` scheduling class.

- `SCHED_RR`

  Round-Robin; threads scheduled to this policy, if not pre-empted by a higher priority, will execute for a time period determined by the system. Threads that have a contention scope of system (`PTHREAD_SCOPE_SYSTEM`) are in real-time (`RT`) scheduling class and the calling process must have an effective user id of `0`. `SCHED_RR` for threads that have a contention scope of process (`PTHREAD_SCOPE_PROCESS`) is based on the `TS` scheduling class.

Prototype:

```
int pthread_attr_setschedparam(pthread_attr_t *tattr,
    const struct sched_param *param);

#include <pthread.h>

pthread_attr_t tattr;
int newprio;
sched_param param;
newprio = 30;

/* set the priority; others are unchanged */
param.sched_priority = newprio;

/* set the new scheduling param */
ret = pthread_attr_setschedparam (&tattr, &param);
```

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following conditions occur, the function fails and returns the corresponding value.

EINVAL

   The value of *param* is NULL or *tattr* is invalid.

You can manage pthreads priority two ways. You can set the priority attribute before creating a child thread, or you can change the priority of the parent thread and then change it back.

Get Scheduling Parameters

pthread_attr_getschedparam(3T)

`pthread_attr_getschedparam`(3T) returns the scheduling parameters defined by `pthread_attr_setschedparam( )`.

Prototype:

```
int pthread_attr_getschedparam(pthread_attr_t *tattr,
    const struct sched_param *param);

#include <pthread.h>

pthread_attr_t attr;
struct sched_param param;
int ret;

/* get the existing scheduling param */
ret = pthread_attr_getschedparam (&tattr, &param);
```

Return Values

`pthread_attr_setschedparam( )` returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

EINVAL

   The value of *param* is NULL or *tattr* is invalid.

Creating a Thread With a Specified Priority

You can set the priority attribute before creating the thread. The child thread is created with the new priority that is specified in the `sched_param` structure (this structure also contains other scheduling information).

It is always a good idea to get the existing parameters, change the priority, xxx the thread, and then reset the priority.

Code Example 3–2 shows an example of this.

CODE EXAMPLE 3–2   Creating a Prioritized Thread

```
#include <pthread.h>
#include <sched.h>

pthread_attr_t tattr;
pthread_t tid;
int ret;
int newprio = 20;
sched_param param;

/* initialized with default attributes */
ret = pthread_attr_init (&tattr);

/* safe to get existing scheduling param */
ret = pthread_attr_getschedparam (&tattr, &param);

/* set the priority; others are unchanged */
param.sched_priority = newprio;

/* setting the new scheduling param */
ret = pthread_attr_setschedparam (&tattr, &param);

/* with new priority specified */
ret = pthread_create (&tid, &tattr, func, arg);
```

Set Stack Size

pthread_attr_setstacksize(3T)

 pthread_attr_setstacksize(3T) sets the thread stack size.

The *stacksize* attribute defines the size of the stack (in bytes) that the system will allocate. The size should not be less than the system-defined minimum stack size. See "About Stacks" on page 71 for more information.

Prototype:

```
int pthread_attr_setstacksize(pthread_attr_t *tattr, int size);

#include <pthread.h>
```

```
pthread_attr_t tattr;
int size;
int ret;

size = (PTHREAD_STACK_MIN + 0x4000);

/* setting a new size */
ret = pthread_attr_setstacksize(&tattr, size);
```

In the example above, *size* contains the number of bytes for the stack that the new thread uses. If *size* is zero, a default size is used. In most cases, a zero value works best.

PTHREAD_STACK_MIN is the amount of stack space required to start a thread. This does not take into consideration the threads routine requirements that are needed to execute application code.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

EINVAL

The value returned is less than the value of PTHREAD_STACK_MIN, or exceeds a system-imposed limit, or *tattr* is not valid.

Get Stack Size

pthread_attr_getstacksize(3T)

pthread_attr_getstacksize(3T) returns the stack size set by pthread_attr_setstacksize().

Prototype:

```
int pthread_attr_getstacksize(pthread_attr_t *tattr, size_t *size);

#include <pthread.h>

pthread_attr_t tattr;
int size;
int ret;

/* getting the stack size */
ret = pthread_attr_getstacksize(&tattr, &size);
```

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

EINVAL

   The value returned is less than the value of PTHREAD_STACK_MIN, or exceeds a system-imposed limit.

About Stacks

Typically, thread stacks begin on page boundaries and any specified size is rounded up to the next page boundary. A page with no access permission is appended to the top of the stack so that most stack overflows result in sending a SIGSEGV signal to the offending thread. Thread stacks allocated by the caller are used as is.

When a stack is specified, the thread should also be created PTHREAD_CREATE_JOINABLE. That stack cannot be freed until the pthread_join(3T) call for that thread has returned, because the thread's stack cannot be freed until the thread has terminated. The only reliable way to know if such a thread has terminated is through pthread_join(3T).

Generally, you do not need to allocate stack space for threads. The threads library allocates 1 Mbyte of virtual memory for each thread's stack with no swap space reserved. (The library uses the MAP_NORESERVE option of mmap() to make the allocations.)

Each thread stack created by the threads library has a red zone. The library creates the red zone by appending a page to the top of a stack to catch stack overflows. This page is invalid and causes a memory fault if it is accessed. Red zones are appended to all automatically allocated stacks whether the size is specified by the application or the default size is used.

Note - Because runtime stack requirements vary, you should be absolutely certain that the specified stack will satisfy the runtime requirements needed for library calls and dynamic linking.

There are very few occasions when it is appropriate to specify a stack, its size, or both. It is difficult even for an expert to know if the right size was specified. This is because even a program compliant with ABI standards cannot determine its stack size statically. Its size is dependent on the needs of the particular runtime environment in which it executes.

Building Your Own Stack

When you specify the size of a thread stack, be sure to account for the allocations needed by the invoked function and by each function called. The accounting should include calling sequence needs, local variables, and information structures.

Occasionally you want a stack that is a bit different from the default stack. An obvious situation is when the thread needs more than one megabyte of stack space. A less obvious situation is when the default stack is too large. You might be creating thousands of threads and not have enough virtual memory to handle the gigabytes of stack space that this many default stacks require.

The limits on the maximum size of a stack are often obvious, but what about the limits on its minimum size? There must be enough stack space to handle all of the stack frames that are pushed onto the stack, along with their local variables, and so on.

You can get the absolute minimum limit on stack size by calling the macro PTHREAD_STACK_MIN, which returns the amount of stack space required for a thread that executes a NULL procedure. Useful threads need more than this, so be very careful when reducing the stack size.

```
#include <pthread.h>

pthread_attr_t tattr;
pthread_t tid;
int ret;

int size = PTHREAD_STACK_MIN + 0x4000;

/* initialized with default attributes */
ret = pthread_attr_init(&tattr);

/* setting the size of the stack also */
ret = pthread_attr_setstacksize(&tattr, size);

/* only size specified in tattr*/
ret = pthread_create(&tid, &tattr, start_routine, arg);
```

When you allocate your own stack, be sure to append a red zone to its end by calling mprotect(2).

Set Stack Address

pthread_attr_setstackaddr(3T)

pthread_attr_setstackaddr(3T) sets the thread stack address.

The *stackaddr* attribute defines the base of the thread's stack. If this is set to non-null (NULL is the default) the system initializes the stack at that address.

```
Prototype:

int pthread_attr_setstackaddr(pthread_attr_t *tattr,void *stackaddr);

#include <pthread.h>

pthread_attr_t tattr;
void *base;
int ret;

base = (void *) malloc(PTHREAD_STACK_MIN + 0x4000);

/* setting a new address */
ret = pthread_attr_setstackaddr(&tattr, base);
```

In the previous example, *base* contains the address for the stack that the new thread uses. If *base* is NULL, then pthread_create(3T) allocates a stack for the new thread with at least PTHREAD_STACK_MIN bytes.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

```
EINVAL
```

    The value of *base* or *tattr* is incorrect.

This example shows how to create a thread with a custom stack address.

```
#include <pthread.h>

pthread_attr_t tattr;
pthread_t tid;
int ret;
void *stackbase;

stackbase = (void *) malloc(size);

/* initialized with default attributes */
ret = pthread_attr_init(&tattr);

/* setting the base address in the attribute */
ret = pthread_attr_setstackaddr(&tattr, stackbase);

/* only address specified in attribute tattr */
ret = pthread_create(&tid, &tattr, func, arg);
```

This example shows how to create a thread with both a custom stack address and a custom stack size.

```
#include <pthread.h>
```

```
pthread_attr_t tattr;
pthread_t tid;
int ret;
void *stackbase;

int size = PTHREAD_STACK_MIN + 0x4000;
stackbase = (void *) malloc(size);

/* initialized with default attributes */
ret = pthread_attr_init(&tattr);

/* setting the size of the stack also */
ret = pthread_attr_setstacksize(&tattr, size);

/* setting the base address in the attribute */
ret = pthread_attr_setstackaddr(&tattr, stackbase);

/* address and size specified */
ret = pthread_create(&tid, &tattr, func, arg);
```

Get Stack Address

pthread_attr_getstackaddr(3T)

 `pthread_attr_getstackaddr`(3T) returns the thread stack address set by
`pthread_attr_setstackaddr( )`.

Prototype:

```
int pthread_attr_getstackaddr(pthread_attr_t *tattr,void * *stackaddr);

#include <pthread.h>

pthread_attr_t tattr;
void *base;
int ret;

/* getting a new address */
ret = pthread_attr_getstackaddr (&tattr, *base);
```

Return Values

Returns zero after completing successfully. Any other returned value indicates that
an error occurred. If the following condition occurs, the function fails and returns the
corresponding value.

EINVAL

   The value or *base* or *tattr* is incorrect.

Programming with Synchronization Objects

This chapter describes the synchronization types available with threads and discusses when and how to use synchronization.

- "Mutual Exclusion Lock Attributes" on page 76
- "Using Mutual Exclusion Locks" on page 93
- "Condition Variable Attributes" on page 105
- "Using Condition Variables" on page 110
- "Semaphores" on page 122
- "Read-Write Lock Attributes" on page 130
- "Set Mutex Attribute's Priority Ceiling" on page 87
- "Synchronization Across Process Boundaries" on page 139
- "Interprocess Locking Without the Threads Library" on page 141
- "Comparing Primitives" on page 141

Synchronization objects are variables in memory that you access just like data. Threads in different processes can communicate with each other through synchronization objects placed in threads-controlled shared memory, even though the threads in different processes are generally invisible to each other.

Synchronization objects can also be placed in files and can have lifetimes beyond that of the creating process.

The available types of synchronization objects are:

- Mutex Locks
- Condition Variables
- Semaphores

Here are situations that can benefit from the use of synchronization:

- When synchronization is the only way to ensure consistency of shared data.

- When threads in two or more processes can use a single synchronization object jointly. Note that the synchronization object should be initialized by only one of the cooperating processes, because reinitializing a synchronization object sets it to the *unlocked* state.

- When synchronization can ensure the safety of mutable data.

- When a process can map a file and have a thread in this process get a record's lock. Once the lock is acquired, any other thread in any process mapping the file that tries to acquire the lock is blocked until the lock is released.

- Even when accessing a single primitive variable, such as an integer. On machines where the integer is not aligned to the bus data width or is larger than the data width, a single memory load can use more than one memory cycle. While this cannot happen on the SPARC® Platform Edition architecture, portable programs cannot rely on this.

Note - On 32-bit architectures a `long long` is not atomic[1] and is read and written as two 32-bit quantities. The types `int`, `char`, `float`, and pointers are atomic on SPARC Platform Edition machines and Intel Architecture machines.

Mutual Exclusion Lock Attributes

Use mutual exclusion locks (mutexes) to serialize thread execution. Mutual exclusion locks synchronize threads, usually by ensuring that only one thread at a time executes a critical section of code. Mutex locks can also preserve single-threaded code.

To change the default mutex attributes, you can declare and initialize an attribute object. Often, the mutex attributes are set in one place at the beginning of the application so they can be located quickly and modified easily. Table 4–1 lists the functions discussed in this section that manipulate mutex attributes.

---

1. An *atomic* operation cannot be divided into smaller operations.

TABLE 4–1 Mutex Attributes Routines

Operation	Destination Discussion
Initialize a mutex mttribute object	"pthread_mutexattr_init(3T)" on page 78
Destroy a mutex attribute object	"pthread_mutexattr_destroy(3T)" on page 79
Set the scope of a mutex	"pthread_mutexattr_setpshared(3T)" on page 80
Get the scope of a mutex	"pthread_mutexattr_getpshared(3T)" on page 81
Set the mutex type attribute	"pthread_mutexattr_settype(3T)" on page 81
Get the mutex type attribute	"pthread_mutexattr_gettype(3T)" on page 83
Set mutex attribute's protocol	"pthread_mutexattr_setprotocol(3T)" on page 83
Get mutex attribute's protocol	"pthread_mutexattr_getprotocol(3T)" on page 86
Set mutex attribute's priority ceiling	"pthread_mutexattr_setprioceiling(3T)" on page 87
Get mutex attribute's priority ceiling	"pthread_mutexattr_getprioceiling(3T)" on page 88
Set mutex's priority ceiling	"pthread_mutex_setprioceiling(3T)" on page 89
Get mutex's priority ceiling	"pthread_mutex_getprioceiling(3T)" on page 90
Set mutex's robust attribute	
Get mutex's robust attribute	

The differences between Solaris threads and POSIX threads, when defining the scope of a mutex, are shown in Table 4–2.

TABLE 4–2 Mutex Scope Comparison

Solaris	POSIX	Definition
USYNC_PROCESS	PTHREAD_PROCESS_SHARED	Use to synchronize threads in this and other processes
USYNC_PROCESS_ROBUST	No POSIX equivalent	Use to *robustly* synchronize threads between processes
USYNC_THREAD	PTHREAD_PROCESS_PRIVATE	Use to synchronize threads in this process only

Initialize a Mutex Attribute Object

pthread_mutexattr_init(3T)

Use pthread_mutexattr_init(3T) to initialize attributes associated with this object to their default values. Storage for each attribute object is allocated by the threads system during execution.

The default value of the *pshared* attribute when this function is called is PTHREAD_PROCESS_PRIVATE, which means that the initialized mutex can be used within a process.

```
Prototype:
int pthread_mutexattr_init(pthread_mutexattr_t *mattr);

#include <pthread.h>

pthread_mutexattr_t mattr;
int ret;

/* initialize an attribute to default value */
ret = pthread_mutexattr_init(&mattr);
```

mattr is an opaque type that contains a system-allocated attribute object. The possible values of *mattr*'s scope are PTHREAD_PROCESS_PRIVATE (the default) and PTHREAD_PROCESS_SHARED.

Before a mutex attribute object can be reinitialized, it must first be destroyed by a call to pthread_mutexattr_destroy(3T). The pthread_mutexattr_init()

call results in the allocation of an opaque object. If the object is not destroyed, a memory leak will result.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If either of the following conditions occurs, the function fails and returns the corresponding value.

ENOMEM

There is not enough memory to initialize the mutex attributes object.

Destroy a Mutex Attribute Object

pthread_mutexattr_destroy(3T)

 pthread_mutexattr_destroy(3T) deallocates the storage space used to maintain the attribute object created by pthread_mutexattr_init().

```
Prototype:
int pthread_mutexattr_destroy(pthread_mutexattr_t *mattr)

#include <pthread.h>

pthread_mutexattr_t mattr;
int ret;

/* destroy an attribute */
ret = pthread_mutexattr_destroy(&mattr);
```

Return Values

pthread_mutexattr_destroy() returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

EINVAL

The value specified by *mattr* is invalid.

Set the Scope of a Mutex

pthread_mutexattr_setpshared(3T)

`pthread_mutexattr_setpshared`(3T) sets the scope of the mutex variable.

The scope of a mutex variable can be either process private (intraprocess) or system wide (interprocess). If the mutex is created with the pshared attribute set to the `PTHREAD_PROCESS_SHARED` state, and it exists in shared memory, it can be shared among threads from more than one process. This is equivalent to the `USYNC_PROCESS` flag in `mutex_init()` in the original Solaris threads.

```
Prototype:
int pthread_mutexattr_setpshared(pthread_mutexattr_t *mattr,
    int pshared);

#include <pthread.h>

pthread_mutexattr_t mattr;
int ret;

ret = pthread_mutexattr_init(&mattr);
/*
 * resetting to its default value: private
 */
ret = pthread_mutexattr_setpshared(&mattr,
    PTHREAD_PROCESS_PRIVATE);
```

If the mutex pshared attribute is set to `PTHREAD_PROCESS_PRIVATE`, only those threads created by the same process can operate on the mutex.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

   The value specified by *mattr* is invalid.

Get the Scope of a Mutex

pthread_mutexattr_getpshared(3T)

`pthread_mutexattr_getpshared`(3T) returns the scope of the mutex variable defined by `pthread_mutexattr_setpshared( )`.

```
Prototype:
int pthread_mutexattr_getpshared(pthread_mutexattr_t *mattr,
    int *pshared);

#include <pthread.h>

pthread_mutexattr_t mattr;
int pshared, ret;

/* get pshared of mutex */
ret = pthread_mutexattr_getpshared(&mattr, &pshared);
```

Get the current value of *pshared* for the attribute object *mattr*. It is either `PTHREAD_PROCESS_SHARED` or `PTHREAD_PROCESS_PRIVATE`.

Return Values

Returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

   The value specified by *mattr* is invalid.

Set the Mutex Type Attribute

pthread_mutexattr_settype(3T)

```
#include <pthread.h>

int pthread_mutexattr_settype(pthread_mutexattr_t  *attr , int type);
```

`pthread_mutexattr_settype`(3T) sets the mutex *type* attribute. The default value of the type attribute is `PTHREAD_MUTEX_DEFAULT`.

The *type* argument specifies the type of mutex. Valid mutex types include:

`PTHREAD_MUTEX_NORMAL`

This type of mutex does not detect deadlock. A thread attempting to relock this mutex without first unlocking it will deadlock. Attempting to unlock a mutex locked by a different thread results in undefined behavior. Attempting to unlock an unlocked mutex results in undefined behavior.

PTHREAD_MUTEX_ERRORCHECK

This type of mutex provides error checking. A thread attempting to relock this mutex without first unlocking it will return with an error. A thread attempting to unlock a mutex which another thread has locked will return with an error. A thread attempting to unlock an unlocked mutex will return with an error.

PTHREAD_MUTEX_RECURSIVE

A thread attempting to relock this mutex without first unlocking it will succeed in locking the mutex. The relocking deadlock which can occur with mutexes of type PTHREAD_MUTEX_NORMAL cannot occur with this type of mutex. Multiple locks of this mutex require the same number of unlocks to release the mutex before another thread can acquire the mutex. A thread attempting to unlock a mutex which another thread has locked will return with an error. A thread attempting to unlock an unloc ked mutex will return with an error. This type of mutex is only supported for mutexes whose process shared attribute is PTHREAD_PROCESS_PRIVATE.

PTHREAD_MUTEX_DEFAULT

Attempting to recursively lock a mutex of this type results in undefined behaviour. Attempting to unlock a mutex of this type which was not locked by the calling thread results in undefined behaviour. Attempting to unlock a mutex of this type which is not locked results in undefined behaviour. An implementation is allowed to map this mutex to one of the other mutex types. (For Solaris threads, PTHREAD_PROCESS_DEFAULT is mapped to PTHREAD_PROCESS_NORMAL.)

Return Values

If successful, the pthread_mutexattr_settype function returns zero. Otherwise, an error number is returned to indicate the error.

EINVAL

The value *type* is invalid.

EINVAL

The value specified by *attr* is invalid.

Get the Mutex Type Attribute

pthread_mutexattr_gettype(3T)

```
#include <pthread.h>

int pthread_mutexattr_gettype(pthread_mutexattr_t  *attr , int  *type);
```

 pthread_mutexattr_gettype(3T) gets the mutex *type* attribute set by pthread_mutexattr_settype(). The default value of the type attribute is PTHREAD_MUTEX_DEFAULT.

The *type* argument specifies the type of mutex. Valid mutex types include:

- PTHREAD_MUTEX_NORMAL

- PTHREAD_MUTEX_ERRORCHECK

- PTHREAD_MUTEX_RECURSIVE

- PTHREAD_MUTEX_DEFAULT

For a description of each type, see "pthread_mutexattr_settype(3T)" on page 81.

Set Mutex Attribute's Protocol

pthread_mutexattr_setprotocol(3T)

pthread_mutexattr_setprotocol(3T) sets the protocol attribute of a mutex attribute object.

```
#include <pthread.h>

int pthread_mutexattr_setprotocol(pthread_mutexattr_t *attr, int protocol);
```

attr points to a mutex attribute object created by an earlier call to pthread_mutexattr_init().

protocol defines the protocol applied to the mutex attribute object.

The value of *protocol*, defined in pthread.h, can be: PTHREAD_PRIO_NONE, PTHREAD_PRIO_INHERIT, or PTHREAD_PRIO_PROTECT.

- PTHREAD_PRIO_NONE

  A thread's priority and scheduling are not affected by the mutex ownership.

- PTHREAD_PRIO_INHERIT

This protocol value affects a thread's (such as thrd1) priority and scheduling when higher-priority threads block on one or more mutexes owned by thrd1 where those mutexes are initialized with PTHREAD_PRIO_INHERIT. thrd1 runs with the higher of its priority or the highest priority of any thread waiting on any of the mutexes owned by thrd1.

If thrd1 blocks on a mutex owned by another thread, thrd3, the same priority inheritance effect recursively propagates to thrd3.

Use PTHREAD_PRIO_INHERIT to avoid priority inversion. Priority inversion occurs when a low-priority thread holds a lock that a higher-priority thread wants. Because the higher-priority thread cannot continue until the lower-priority thread releases the lock, each thread is treated as if it had the inverse of its intended priority.

If the symbol _POSIX_THREAD_PRIO_INHERIT is defined, for a mutex initialized with the protocol attribute value PTHREAD_PRIO_INHERIT, the following actions occur in the Solaris Operating Environment when the owner of that mutex dies:

Note - The behavior on owner death depends on the value of the *robustness* argument of pthread_mutexattr_setrobust_np().

- The mutex is unlocked.
- The next owner of the mutex acquires it with an error return of EOWNERDEAD.
- The next owner of the mutex should try to make the state protected by the mutex consistent—the state might have been left inconsistent when the previous owner died. If the owner is successful in making the state consistent, call pthread_mutex_init() for the mutex and unlock the mutex.

Note - If pthread_mutex_init() is called on a previously initialized, but not yet destroyed mutex, the mutex is not reiintialized.

- If the owner is unable to make the state consistent, do *not* call pthread_mutex_init(), but unlock the mutex. In this event, all waiters will be woken up and all subsequent calls to pthread_mutex_lock() will fail to acquire the mutex and return an error code of ENOTRECOVERABLE. You can now make the mutex state consistent by calling pthread_mutex_destroy() to uninitialize the mutex and calling pthread_mutex_init() to reinitialize it.
- If the thread that acquired the lock with EOWNERDEAD dies, the next owner acquires the lock with an error code of EOWNERDEAD.

- PTHREAD_PRIO_PROTECT

This protocol value affects a thread's (such as thrd2) priority and scheduling when the thread owns one or more mutexes initialized with PTHREAD_PRIO_PROTECT. thrd2 runs with the higher of its priority or the

highest-priority ceiling of all mutexes it owns. Higher-priority threads blocked on any of the mutexes, owned by `thrd2`, have no effect on the scheduling of `thrd2`.

When a thread owns a mutex that is intialized with `PTHREAD_PRIO_INHERIT` or `PTHREAD_PRIO_PROTECT`, and that thread's original priority changes, such as by a call to `sched_setparam()`, the scheduler does not move the thread to the tail of the scheduling queue at it's new priority. Similarly, when a thread unlocks a mutex that is intialized with `PTHREAD_PRIO_INHERIT` or `PTHREAD_PRIO_PROTECT`, and that thread's original priority changes, the scheduler does not move the thread to the tail of the scheduling queue at it's new priority.

If a thread simultaneously owns several mutexes initialized with a mix of `PTHREAD_PRIO_INHERIT` and `PTHREAD_PRIO_PROTECT`, it executes at the highest priority obtained by either of these protocols.

Return Values

On successful completion, `pthread_mutexattr_setprotocol()` returns 0. Any other returned value indicates that an error occurred.

If either of the following conditions occurs, `pthread_mutexattr_setprotocol()` fails and returns the corresponding value.

ENOSYS

Neither of the options `_POSIX_THREAD_PRIO_INHERIT` and `_POSIX_THREAD_PRIO_PROTECT` is defined and the implementation does not support the function.

ENOTSUP

The value specified by *protocol* is an unsupported value.

If either of the following conditions occurs, `pthread_mutexattr_setprotocol()` might fail and return the corresponding value.

EINVAL

The value specified by *attr* or *protocol* is not valid.

EPERM

The caller does not have the privilege to perform the operation.

Get Mutex Attribute's Protocol

pthread_mutexattr_getprotocol(3T)

pthread_mutexattr_getprotocol(3T) gets the protocol attribute of a mutex attribute object.

```
#include <pthread.h>
```

```
int pthread_mutexattr_getprotocol(const pthread_mutexattr_t *attr, int *protocol);
```

attr points to a mutex attribute object created by an earlier call to pthread_mutexattr_init().

protocol contains the protocol attribute: PTHREAD_PRIO_NONE, PTHREAD_PRIO_INHERIT, or PTHREAD_PRIO_PROTECT.

Return Values

On successful completion, pthread_mutexattr_getprotocol() returns 0. Any other returned value indicates that an error occurred.

If the following condition occurs, pthread_mutexattr_getprotocol() fails and returns the corresponding value.

ENOSYS

Neither of the options, _POSIX_THREAD_PRIO_INHERIT nor _POSIX_THREAD_PRIO_PROTECT is defined and the implementation does not support the function.

If either of the following conditions occurs, pthread_mutexattr_getprotocol() might fail and return the corresponding value.

EINVAL

The value specified by *attr* is invalid.

EPERM

The caller does not have the privilege to perform the operation.

Set Mutex Attribute's Priority Ceiling

pthread_mutexattr_setprioceiling(3T)

pthread_mutexattr_setprioceiling(3T) sets the priority ceiling attribute of a mutex attribute object.

```
#include <pthread.h>
```

```
int pthread_mutexattr_setprioceiling(pthread_mutexattr_t *attr, int prioceiling, int *oldceiling);
```

attr points to a mutex attribute object created by an earlier call to pthread_mutexattr_init( ).

Note - The *attr* mutex attribute object includes the priority ceiing attribute only if the symbol _POSIX_THREAD_PRIO_PROTECT is defined.

---

prioceiling specifies the priority ceiling of initialized mutexes. The ceiling defines the minimum priority level at which the critical section guarded by the mutex is executed. *prioceiling* will be within the maximum range of priorities defined by SCHED_FIFO. To avoid priority inversion, *prioceiling* will be set to a priority higher than or equal to the highest priority of all the threads that might lock the particular mutex.

oldceiling contains the old priority ceiling value.

Return Values

On successful completion, pthread_mutexattr_setprioceiling( ) returns 0. Any other returned value indicates that an error occurred.

If any of the following conditions occurs, pthread_mutexattr_setprioceiling( ) fails and returns the corresponding value.

ENOSYS

   The option _POSIX_THREAD_PRIO_PROTECT is not defined and the implementation does not support the function.

If either of the following conditions occurs, pthread_mutexattr_setprioceiling( ) might fail and return the corresponding value.

EINVAL

   The value specified by *attr* or *prioceiling* is invalid.

EPERM

The caller does not have the privilege to perform the operation.

Get Mutex Attribute's Priority Ceiling

pthread_mutexattr_getprioceiling(3T)

pthread_mutexattr_getprioceiling(3T) gets the priority ceiling attribute of a mutex attribute object.

```
#include <pthread.h>
```

```
int pthread_mutexattr_getprioceiling(const pthread_mutexattr_t *attr, int *prioceiling);
```

attr designates the attribute object created by an earlier call to pthread_mutexattr_init().

Note - The *attr* mutex attribute object includes the priority ceiing attribute only if the symbol _POSIX_THREAD_PRIO_PROTECT is defined.

---

pthread_mutexattr_getprioceiling() returns the priority ceiling of initialized mutexes in *prioceiling*. The ceiling defines the minimum priority level at which the critical section guarded by the mutex is executed. *prioceiling* will be within the maximum range of priorities defined by SCHED_FIFO. To avoid priority inversion, *prioceiling* will be set to a priority higher than or equal to the highest priority of all the threads that might lock the particular mutex.

Return Values

On successful completion, pthread_mutexattr_getprioceiling() returns 0. Any other returned value indicates that an error occurred.

If any of the following conditions occurs, pthread_mutexattr_getprioceiling() fails and returns the corresponding value.

ENOSYS

   The option _POSIX_THREAD_PRIO_PROTECT is not defined and the implementation does not support the function.

If either of the following conditions occurs, pthread_mutexattr_getprioceiling() might fail and return the corresponding value.

EINVAL

The value specified by *attr* is invalid.

EPERM

The caller does not have the privilege to perform the operation.

Set Mutex's Priority Ceiling

pthread_mutex_setprioceiling(3T)

pthread_mutex_setprioceiling(3T) sets the priority ceiling of a mutex.

```
#include <pthread.h>
```

```
int pthread_mutex_setprioceiling(pthread_mutexatt_t *mutex, int prioceiling, int *old_ceiling);
```

pthread_mutex_setprioceiling() changes the priority ceiling, *prioceiling*, of a mutex, *mutex*. pthread_mutex_setprioceiling() locks the mutex if it is unlocked, or blocks until it can successfully lock the mutex, changes the priority celing of the mutex and releases the mutex. The process of locking the mutex need not adhere to the priority protect protocol.

Note - The mutex attribute object, *mutex*, includes the priority ceiing attribute only if the symbol _POSIX_THREAD_PRIO_PROTECT is defined.

If pthread_mutex_setprioceiling() succeeds, the previous value of the priority ceiling is returned in *old_ceiling*. If pthread_mutex_setprioceiling() fails, the mutex priority ceiling remains unchanged.

Return Values

On successful completion, pthread_mutex_setprioceiling() returns 0. Any other returned value indicates that an error occurred.

If the following condition occurs, pthread_mutexatt_setprioceiling() fails and returns the corresponding value.

ENOSYS

The option _POSIX_THREAD_PRIO_PROTECT is not defined and the implementation does not support the function.

If any of the following conditions occurs, pthread_mutex_setprioceiling() might fail and return the corresponding value.

EINVAL

The priority requested by *prioceiling* is out of range.

EINVAL

The value specified by *mutex* does not refer to a currently existing mutex.

ENOSYS

The implementation does not support the priority ceiling protocol for mutexes.

EPERM

The caller does not have the privilege to perform the operation.

Get Mutex's Priority Ceiling

pthread_mutex_getprioceiling(3T)

pthread_mutex_getprioceiling(3T) gets the priority ceiling of a mutex.

```
#include <pthread.h>

int pthread_mutex_getprioceiling(const pthread_mutexatt_t *mutex, int *prioceiling);
```

`pthread_mutex_getprioceiling()` returns the priority ceiling, *prioceiling* of a mutex *mutex*.

Return Values

On successful completion, `pthread_mutex_getprioceiling()` returns 0. Any other returned value indicates that an error occurred.

If any of the following conditions occurs, `pthread_mutexatt_getprioceiling()` fails and returns the corresponding value.

ENOSYS

The option `_POSIX_THREAD_PRIO_PROTECT` is not defined and the implementation does not support the function.

If any of the following conditions occurs, `pthread_mutex_getprioceiling()` might fail and return the corresponding value.

EINVAL

The value specified by *mutex* does not refer to a currently existing mutex.

ENOSYS

The implementation does not support the priority ceiling protocol for mutexes.

EPERM

The caller does not have the privilege to perform the operation.

Set Mutex's Robust Attribute

pthread_mutexattr_setrobust_np(3T)

pthread_mutexattr_setrobust_np(3T) sets the robust attribute of a mutex attribute object.

```
#include <pthread.h>
```

```
int pthread_mutexattr_setrobust_np(pthread_mutexatt_t *attr, int *robustness);
```

Note - pthread_mutexattr_setrobust_np() applies only if the symbol
_POSIX_THREAD_PRIO_INHERIT is defined.

---

attr points to the mutex attribute object previously created by a call to
pthread_mutexattr_init().

robustness defines the behavior when the owner of the mutex dies. The value of
robustness, defined in pthread.h, is PTHREAD_MUTEX_ROBUST_NP or
PTHREAD_MUTEX_STALLED_NP. The default value is
PTHREAD_MUTEX_STALLED_NP.

- PTHREAD_MUTEX_ROBUST_NP

  When the owner of the mutex dies, all subsequent calls to
  pthread_mutex_lock() are blocked from progress in an unspecified manner.

- PTHREAD_MUTEX_STALLED_NP

  When the owner of the mutex dies, the mutex is unlocked. The next owner of this
  mutex acquires it with an error return of EOWNWERDEAD.

Note - Your application must check the return code from pthread_mutex_lock()
for a mutex of this type.

- The new owner of this mutex should make the state protected by the mutex
  consistent; this state might have been left inconsistent when the previous
  owner died.
- If the new owner is able to make the state consistent, call
  pthread_mutex_consistent_np() for the mutex, and unlock the mutex.

- If the new owner is *not* able to make the state consistent, do *not* call
  `pthread_mutex_consistent_np()` for the mutex, but unlock the mutex.

  All waiters are woken up and all subsequent calls to
  `pthread_mutex_lock()` fail to acquire the mutex. The return code is
  `ENOTRECOVERABLE`. The mutex can be made consistent by calling
  `pthread_mutex_destroy()` to unitialize the mutex, and calling
  `pthread_mutex_int()` to reinitialize it.

If the thread that acquire the lock with `EOWNERDEAD` died, the next owner acquires
the lock with an `EOWNERDEAD` return code.

Return Values

On successful completion, `pthread_mutexattr_setrobust_np()` returns 0. Any
other returned value indicates that an error occurred.

If any of the following conditions occurs, `pthread_mutexattr_setrobust_np()`
fails and returns the corresponding value.

`ENOSYS`

The option `_POSIX_THREAD_PRIO__INHERIT` is not defined or the
implementation does not support `pthread_mutexattr_setrobust_np()`.

`ENOTSUP`

The value specified by *robustness* is not supported.

`pthread_mutexattr_setrobust_np()` might fail if:

`EINVAL`

The value specified by *attr* or *robustness* is invalid.

Get Mutex's Robust Attribute

pthread_mutexattr_getrobust_np(3T)

pthread_mutexattr_getrobust_np(3T) gets the robust attribute of a mutex attribute
object.

```
#include <pthread.h>

int pthread_mutexattr_getrobust_np(pthread_mutexatt_t *attr, int *robustness);
```

> **Note -** pthread_mutexattr_getrobust_np() applies only if the symbol
> _POSIX_THREAD_PRIO_INHERIT is defined.

attr points to the mutex attribute object previously created by a call to
pthread_mutexattr_init().

robustness is the value of the robust attribute of a mutex attribute object.

Return Values

On successful completion, pthread_mutexattr_getrobust_np() returns 0. Any
other returned value indicates that an error occurred.

If any of the following conditions occurs, pthread_mutexattr_getrobust_np()
fails and returns the corresponding value.

ENOSYS

    The option _POSIX_THREAD_PRIO__INHERIT is not defined or the
    implementation does not support pthread_mutexattr_getrobust_np().

ENOTSUP

    The value specified by *robustness* is not supported.

pthread_mutexattr_getrobust_np() might fail if:

EINVAL

    The value specified by *attr* or *robustness* is invalid.

Using Mutual Exclusion Locks

Table 4–3 lists the functions discussed in this chapter that manipulate mutex locks.

TABLE 4–3   Routines for Mutual Exclusion Locks

Operation	Destination Discussion
Initialize a mutex	
Lock a mutex	pthread_mutex_lock(3T)

TABLE 4–3   Routines for Mutual Exclusion Locks   *(continued)*

Operation	Destination Discussion
Unlock a mutex	"pthread_mutex_unlock(3T)" on page 98
Lock with a nonblocking mutex	"pthread_mutex_trylock(3T)" on page 99
Destroy a mutex	"pthread_mutex_destroy(3T)" on page 101

The default scheduling policy, SCHED_OTHER, does not specify the order in which threads can acquire a lock. When multiple threads are waiting for a mutex, the order of acquisition is undefined. When there is contention, the default behavior is to unblock threads in priority order.

Initialize a Mutex

pthread_mutex_init(3T)

Use pthread_mutex_init(3T) to initialize the mutex pointed at by *mp* to its default value (*mattr* is NULL), or to specify mutex attributes that have already been set with pthread_mutexattr_init(). (For Solaris threads, see "mutex_init(3T)" on page 221.)

```
Prototype:
int pthread_mutex_init(pthread_mutex_t *mp,
    const pthread_mutexattr_t *mattr);

#include <pthread.h>

pthread_mutex_t mp = PTHREAD_MUTEX_INITIALIZER;
pthread_mutexattr_t mattr;
int ret;

/* initialize a mutex to its default value */
ret = pthread_mutex_init(&mp, NULL);

/* initialize a mutex */
ret = pthread_mutex_init(&mp, &mattr);
```

When the mutex is initialized, it is in an unlocked state. The mutex can be in memory shared between processes or in memory private to a process.

> **Note -** The mutex memory must be cleared to zero before initialization.

The effect of *mattr* being NULL is the same as passing the address of a default mutex attribute object, but without the memory overhead.

Statically defined mutexes can be initialized directly to have default attributes with the macro PTHREAD_MUTEX_INITIALIZER.

A mutex lock must not be reinitialized or destroyed while other threads might be using it. Program failure will result if either action is not done correctly. If a mutex is reinitialized or destroyed, the application must be sure the mutex is not currently in use.

Return Values

pthread_mutex_init() returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EBUSY

   The implementation has detected an attempt to reinitialize the object referenced by *mp* (a previously initialized, but not yet destroyed mutex).

EINVAL

   The *mattr* attribute value is invalid. The mutex has not been modified.

EFAULT

   The address for the mutex pointed at by *mp* is invalid.

Make Mutex Consistent

pthread_mutex_consistent_np(3T)

```
#include <pthread.h>
int pthread_mutex_consistent_np(pthread_mutex_t *mutex);
```

> **Note -** pthread_mutex_consistent_np() applies only if the symbol _POSIX_THREAD_PRIO_INHERIT is defined and for mutexes that are initialized with the protocol attribute value PTHREAD_PRIO_INHERIT.

If the owner of a mutex dies, the mutex can become inconsistent.

pthread_mutex_consistent_np makes the mutex object, *mutex*, consistent after the death of its owner.

Call pthread_mutex_lock() to acquire the inconstent mutex. The EOWNWERDEAD return value indicates an inconsistent mutex.

Call pthread_mutex_consistent_np() while holding the mutex acquired by a previuos call to pthread_mutex_lock().

Because the critical section protected by the mutex might have been left in an inconsistent state by the dead owner, make the mutex consistent only if you are able to make the critical section protected by the mutex consistent.

Calls to pthread_mutex_lock(), pthread_mutex_unlock(), and pthread_mutex_trylock() for a consistent mutex behave in the normal manner.

The behavior of pthread_mutex_consistent_np() for a mutex that is *not* inconsistent, or that is not held, is undefined.

Return Values

pthread_mutex_consistent_np() returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

pthread_mutex_consistent_np() fails if:

ENOSYS

   The option _POSIX_THREAD_PRIO_INHERIT is not defined or the implementation does not support pthread_mutex_consistent_np().

pthread_mutex_consistent_np() might fail if:

EINVAL

   The value specified by *mutex* is invalid.

Lock a Mutex

pthread_mutex_lock(3T)

```
Prototype:
int pthread_mutex_lock(pthread_mutex_t *mutex);

#include <pthread.h>
```

```
pthread_mutex_t mutex;
int ret;

ret = pthread_ mutex_lock(&mp); /* acquire the mutex */
```

Use `pthread_mutex_lock`(3T) to lock the mutex pointed to by *mutex*. When `pthread_mutex_lock()` returns, the mutex is locked and the calling thread is the owner. If the mutex is already locked and owned by another thread, the calling thread blocks until the mutex becomes available. (For Solaris threads, see "mutex_lock(3T)" on page 223.)

If the mutex type is `PTHREAD_MUTEX_NORMAL`, deadlock detection is not provided. Attempting to relock the mutex causes deadlock. If a thread attempts to unlock a mutex that it has not locked or a mutex that is unlocked, undefined behaviour results.

If the mutex type is `PTHREAD_MUTEX_ERRORCHECK`, then error checking is provided. If a thread attempts to relock a mutex that it has already locked, an error will be returned. If a thread attempts to unlock a mutex that it has not locked or a mutex that is unlocked, an error will be returned.

If the mutex type is `PTHREAD_MUTEX_RECURSIVE`, then the mutex maintains the concept of a lock count. When a thread successfully acquires a mutex for the first time, the lock count is set to one. Every time a thread relocks this mutex, the lock count is incremented by one. Each time the thread unlocks the mutex, the lock count is decremented by one. When the lock count reaches zero, the mutex becomes available for other threads to acquire. If a thread attempts to unlock a mutex that it has not locked or a mutex which is unlocked, an error will be returned.

If the mutex type is `PTHREAD_MUTEX_DEFAULT`, attempting to recursively lock the mutex results in undefined behavior. Attempting to unlock the mutex if it was not locked by the calling thread results in undefined behavior. Attempting to unlock the mutex if it is not locked results in undefined behavior.

Return Values

`pthread_mutex_lock()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EAGAIN

  The mutex could not be acquired because the maximum number of recursive locks for mutex has been exceeded.

EDEADLK

  The current thread already owns the mutex.

If the symbol `_POSIX_THREAD_PRIO_INHERIT` is defined, the mutex is initialized with the protocol attribute value `PTHREAD_PRIO_INHERIT`, and the *robustness*

argument of `pthread_mutexattr_setrobust_np()` is
`PTHREAD_MUTEX_ROBUST_NP` the function fails and returns:

EOWNERDEAD

The last owner of this mutex died while holding the mutex. This mutex is now
owned by the caller. The caller must attempt to make the state protected by the
mutex consistent.

If the caller is able to make the state consistent, call
`pthread_mutex_consistent_np()` for the mutex and unlock the mutex.
Subsequent calls to `pthread_mutex_lock()` will behave normally.

If the caller is unable to make the state consistent, do not call
`pthread_mutex_init()` for the mutex, but unlock the mutex. Subsequent calls
to `pthread_mutex_lock()` fail to acquire the mutex and return an
`ENOTRECOVERABLE` error code.

If the owner that acquired the lock with `EOWNERDEAD` dies, the next owner
acquires the lock with `EOWNERDEAD`.

ENOTRECOVERABLE

The mutex you are trying to acquire is protecting state left irrecoverable by the
mutex's previous owner that died while holding the lock. The mutex has not been
acquired. This condition can occur when the lock was previously acquired with
`EOWNERDEAD` and the owner was unable to cleanup the state and had unlocked
the mutex without making the mutex state consistent.

ENOMEM

The limit on the number of simultaneously held mutexes has been exceeded.

Unlock a Mutex

pthread_mutex_unlock(3T)

Use `pthread_mutex_unlock`(3T) to unlock the mutex pointed to by *mutex*. (For
Solaris threads, see "mutex_unlock(3T)" on page 223.)

```
Prototype:
int pthread_mutex_unlock(pthread_mutex_t *mutex);

#include <pthread.h>

pthread_mutex_t mutex;
int ret;
```

```
ret = pthread_mutex_unlock(&mutex); /* release the mutex */
```

pthread_mutex_unlock() releases the mutex object referenced by *mutex*. The manner in which a mutex is released is dependent upon the mutex's type attribute. If there are threads blocked on the mutex object referenced by *mutex* when pthread_mutex_unlock() is called, resulting in the mutex becoming available, the scheduling policy is used to determine which thread shall acquire the mutex. (In the case of PTHREAD_MUTEX_RECURSIVE mutexes, the mutex becomes available when the count reaches zero and the calling thread no longer has any locks on this mutex).

Return Values

pthread_mutex_unlock() returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EPERM

  The current thread does not own the mutex.

Lock With a Nonblocking Mutex

pthread_mutex_trylock(3T)

Use pthread_mutex_trylock(3T) to attempt to lock the mutex pointed to by *mutex*. (For Solaris threads, see "mutex_trylock(3T)" on page 224.)

```
Prototype:
int pthread_mutex_trylock(pthread_mutex_t *mutex);

#include <pthread.h>

pthread_mutex_t mutex;
int ret;

ret = pthread_mutex_trylock(&mutex); /* try to lock the mutex */
```

pthread_mutex_trylock() is a nonblocking version of pthread_mutex_lock(). If the mutex object referenced by *mutex* is currently locked (by any thread, including the current thread), the call returns immediately. Otherwise, the mutex is locked and the calling thread is the owner.

Return Values

pthread_mutex_trylock() returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EBUSY

The mutex could not be acquired because the mutex pointed to by *mutex* was already locked.

EAGAIN

The mutex could not be acquired because the maximum number of recursive locks for *mutex* has been exceeded.

If the symbol _POSIX_THREAD_PRIO_INHERIT is defined, the mutex is initialized with the protocol attribute value PTHREAD_PRIO_INHERIT, and the *robustness* argument of pthread_mutexattr_setrobust_np() is PTHREAD_MUTEX_ROBUST_NP the function fails and returns:

EOWNERDEAD

The last owner of this mutex died while holding the mutex. This mutex is now owned by the caller. The caller must attempt to make the state protected by the mutex consistent.

If the caller is able to make the state consistent, call pthread_mutex_consistent_np() for the mutex and unlock the mutex. Subsequent calls to pthread_mutex_lock() will behave normally.

If the caller is unable to make the state consistent, do not call pthread_mutex_init() for the mutex, but unlock the mutex. Subsequent calls to pthread_mutex_trylock() fail to acquire the mutex and return an ENOTRECOVERABLE error code.

If the owner that acquired the lock with EOWNERDEAD dies, the next owner acquires the lock with EOWNERDEAD.

ENOTRECOVERABLE

The mutex you are trying to acquire is protecting state left irrecoverable by the mutex's previous owner that died while holding the lock. The mutex has not been acquired. This condition can occur when the lock was previously acquired with EOWNERDEAD and the owner was unable to cleanup the state and had unlocked the mutex without making the mutex state consistent.

ENOMEM

The limit on the number of simultaneously held mutexes has been exceeded.

Destroy a Mutex

pthread_mutex_destroy(3T)

Use `pthread_mutex_destroy`(3T) to destroy any state associated with the mutex pointed to by *mp*. (For Solaris threads, see "mutex_destroy(3T)" on page 223.)

```
Prototype:
int pthread_mutex_destroy(pthread_mutex_t *mp);

#include <pthread.h>

pthread_mutex_t mp;
int ret;

ret = pthread_mutex_destroy(&mp); /* mutex is destroyed */
```

Note that the space for storing the mutex is not freed.

Return Values

`pthread_mutex_destroy()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occur, the function fails and returns the corresponding value.

```
EINVAL
```

    The value specified by *mp* does not refer to an initialized mutex object.

Mutex Lock Code Examples

Code Example 4–1 shows some code fragments with mutex locking.

CODE EXAMPLE 4–1 Mutex Lock Example

```
#include <pthread.h>

pthread_mutex_t count_mutex;
long long count;

void
increment_count()
{
    pthread_mutex_lock(&count_mutex);
    count = count + 1;
    pthread_mutex_unlock(&count_mutex);
}

long long
```

```
get_count()
{
    long long c;

    pthread_mutex_lock(&count_mutex);
     c = count;
    pthread_mutex_unlock(&count_mutex);
     return (c);
}
```

The two functions in Code Example 4–1 use the mutex lock for different purposes.
The increment_count() function uses the mutex lock simply to ensure an atomic
update of the shared variable. The get_count() function uses the mutex lock to
guarantee that the 64-bit quantity *count* is read atomically. On a 32-bit architecture, a
long long is really two 32-bit quantities.

Reading an integer value is an atomic operation because integer is the common word
size on most machines.

Using Locking Hierarchies

You will occasionally want to access two resources at once. Perhaps you are using
one of the resources, and then discover that the other resource is needed as well.
There could be a problem if two threads attempt to claim both resources but lock the
associated mutexes in different orders. For example, if the two threads lock mutexes
1 and 2 respectively, then a deadlock occurs when each attempts to lock the other
mutex. Code Example 4–2 shows possible deadlock scenarios.

CODE EXAMPLE 4–2   Deadlock

Thread 1	Thread 2
`pthread_mutex_lock(&m1);`	`pthread_mutex_lock(&m2);`
/* use resource 1 */	/* use resource 2 */
`pthread_mutex_lock(&m2);`	`pthread_mutex_lock(&m1);`
/* use resources1 and 2 */	/* use resources 1 and 2 */
`pthread_mutex_unlock(&m2);`	`pthread_mutex_unlock(&m1);`
`pthread_mutex_unlock(&m1);`	`pthread_mutex_unlock(&m2);`

The best way to avoid this problem is to make sure that whenever threads lock multiple mutexes, they do so in the same order. This technique is known as lock hierarchies: order the mutexes by logically assigning numbers to them.

Also, honor the restriction that you cannot take a mutex that is assigned *n* when you are holding any mutex assigned a number greater than *n*.

Note - The `lock_lint` tool can detect the sort of deadlock problem shown in this example. The best way to avoid such deadlock problems is to use lock hierarchies. When locks are always taken in a prescribed order, deadlock should not occur.

However, this technique cannot always be used—sometimes you must take the mutexes in an order other than prescribed. To prevent deadlock in such a situation, use `pthread_mutex_trylock()`. One thread must release its mutexes when it discovers that deadlock would otherwise be inevitable.

CODE EXAMPLE 4–3   Conditional Locking

Thread 1	Thread 2
`pthread_mutex_lock(&m1);` `pthread_mutex_lock(&m2);`	`for (; ;)`
	`{ pthread_mutex_lock(&m2);`
	`if(pthread_mutex_trylock(&m1)==0)`
	/* got it! */
/* no processing */	`break;`
`pthread_mutex_unlock(&m2);`	/* didn't get it */
`pthread_mutex_unlock(&m1);`	`pthread_mutex_unlock(&m2);`
	`}`
	/* get locks; no processing */
	`pthread_mutex_unlock(&m1);`
	`pthread_mutex_unlock(&m2);`

In Code Example 4–3, thread 1 locks mutexes in the prescribed order, but thread 2 takes them out of order. To make certain that there is no deadlock, thread 2 has to take mutex 1 very carefully; if it were to block waiting for the mutex to be released, it is likely to have just entered into a deadlock with thread 1.

To ensure this does not happen, thread 2 calls `pthread_mutex_trylock()`, which takes the mutex if it is available. If it is not, thread 2 returns immediately, reporting

Programming with Synchronization Objects   **103**

failure. At this point, thread 2 must release mutex 2, so that thread 1 can lock it, and then release both mutex 1 and mutex 2.

Nested Locking With a Singly Linked List

Code Example 4–4 and Code Example 4–5 show how to take three locks at once, but prevent deadlock by taking the locks in a prescribed order.

CODE EXAMPLE 4–4   Singly Linked List Structure

```
typedef struct node1 {
    int value;
    struct node1 *link;
    pthread_mutex_t lock;
} node1_t;

node1_t ListHead;
```

This example uses a singly linked list structure with each node containing a mutex. To remove a node from the list, first search the list starting at *ListHead* (which itself is never removed) until the desired node is found.

To protect this search from the effects of concurrent deletions, lock each node before any of its contents are accessed. Because all searches start at *ListHead*, there is never a deadlock because the locks are always taken in list order.

When the desired node is found, lock both the node and its predecessor since the change involves both nodes. Because the predecessor's lock is always taken first, you are again protected from deadlock. Code Example 4–5 shows the C code to remove an item from a singly linked list.

CODE EXAMPLE 4–5   Singly Linked List With Nested Locking

```
node1_t *delete(int value)
{
    node1_t *prev, *current;

    prev = &ListHead;
    pthread_mutex_lock(&prev->lock);

    while ((current = prev->link) != NULL) {
        pthread_mutex_lock(&current->lock);
        if (current->value == value) {
            prev->link = current->link;
            pthread_mutex_unlock(&current->lock);

            pthread_mutex_unlock(&prev->lock);
            current->link = NULL;
            return(current);
        }
        pthread_mutex_unlock(&prev->lock);
        prev = current;
    }
    pthread_mutex_unlock(&prev->lock);
```

```
        return(NULL);
}
```

Nested Locking With a Circular Linked List

Code Example 4–6 modifies the previous list structure by converting it into a circular list. There is no longer a distinguished head node; now a thread might be associated with a particular node and might perform operations on that node and its neighbor. Note that lock hierarchies do not work easily here because the obvious hierarchy (following the links) is circular.

CODE EXAMPLE 4–6   Circular Linked List Structure

```
typedef struct node2 {
    int value;
    struct node2 *link;
    pthread_mutex_t lock;
} node2_t;
```

Here is the C code that acquires the locks on two nodes and performs an operation involving both of them.

CODE EXAMPLE 4–7   Circular Linked List With Nested Locking

```
void Hit Neighbor(node2_t *me) {
   while (1) {
      pthread_mutex_lock(&me->lock);
      if (pthread_mutex_lock(&me->link->lock)!= 0) {
         /* failed to get lock */
         pthread_mutex_unlock(&me->lock);
         continue;
      }
      break;
   }
   me->link->value += me->value;
   me->value /=2;
   pthread_mutex_unlock(&me->link->lock);
   pthread_mutex_unlock(&me->lock);
}
```

Condition Variable Attributes

Use condition variables to atomically block threads until a particular condition is true. Always use condition variables together with a mutex lock.

With a condition variable, a thread can atomically block until a condition is satisfied. The condition is tested under the protection of a mutual exclusion lock (mutex).

When the condition is false, a thread usually blocks on a condition variable and atomically releases the mutex waiting for the condition to change. When another thread changes the condition, it can signal the associated condition variable to cause one or more waiting threads to wake up, acquire the mutex again, and reevaluate the condition.

Condition variables can be used to synchronize threads among processes when they are allocated in memory that can be written to and is shared by the cooperating processes.

The scheduling policy determines how blocking threads are awakened. For the default SCHED_OTHER, threads are awakened in priority order.

The attributes for condition variables must be set and initialized before the condition variables can be used. The functions that manipulate condition variable attributes are listed in Table 4–4.

TABLE 4–4   Condition Variable Attributes

Operation	Destination Discussion
Initialize a condition variable attribute	"pthread_condattr_init(3T)" on page 107
Remove a condition variable attribute	"pthread_condattr_destroy(3T)" on page 108
Set the scope of a condition variable	"pthread_condattr_setpshared(3T)" on page 109
Get the scope of a condition variable	"pthread_condattr_getpshared(3T)" on page 110

The differences between Solaris and POSIX threads, when defining the scope of a condition variable, are shown in Table 4–5.

TABLE 4–5 Condition Variable Scope Comparison

Solaris	POSIX	Definition
USYNC_PROCESS	PTHREAD_PROCESS_SHARED	Use to synchronize threads in this and other processes
USYNC_THREAD	PTHREAD_PROCESS_PRIVATE	Use to synchronize threads in this process only

Initialize a Condition Variable Attribute

pthread_condattr_init(3T)

Use pthread_condattr_init(3T) to initialize attributes associated with this object to their default values. Storage for each attribute object is allocated by the threads system during execution. The default value of the *pshared* attribute when this function is called is PTHREAD_PROCESS_PRIVATE, which means that the initialized condition variable can be used within a process.

```
Prototype:
int pthread_condattr_init(pthread_condattr_t *cattr);

#include <pthread.h>
pthread_condattr_t   cattr;
int ret;

/* initialize an attribute to default value */
ret = pthread_condattr_init(&cattr);
```

cattr is an opaque data type that contains a system-allocated attribute object. The possible values of *cattr*'s scope are PTHREAD_PROCESS_PRIVATE (the default) and PTHREAD_PROCESS_SHARED.

Before a condition variable attribute can be reused, it must first be reinitialized by pthread_condattr_destroy(3T). The pthread_condattr_init() call returns a pointer to an opaque object. If the object is not destroyed, a memory leak will result.

Return Values

`pthread_condattr_init()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When either of the following conditions occurs, the function fails and returns the corresponding value.

ENOMEM

There is not enough memory to initialize the thread attributes object.

EINVAL

The value specified by *cattr* is invalid.

Remove a Condition Variable Attribute

pthread_condattr_destroy(3T)

Use `pthread_condattr_destroy`(3T) to remove storage and render the attribute object invalid.

```
Prototype:
int pthread_condattr_destroy(pthread_condattr_t *cattr);

#include <pthread.h>
pthread_condattr_t cattr;
int ret;

/* destroy an attribute */
ret
 = pthread_condattr_destroy(&cattr);
```

Return Values

`pthread_condattr_destroy()` returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

EINVAL

The value specified by *cattr* is invalid.

Set the Scope of a Condition Variable

pthread_condattr_setpshared(3T)

`pthread_condattr_setpshared`(3T) sets the scope of a condition variable to either process private (intraprocess) or system wide (interprocess). If the condition variable is created with the pshared attribute set to the `PTHREAD_PROCESS_SHARED` state, and it exists in shared memory, it can be shared among threads from more than one process. This is equivalent to the `USYNC_PROCESS` flag in `mutex_init()` in the original Solaris threads.

If the mutex pshared attribute is set to `PTHREAD_PROCESS_PRIVATE` (default value), only those threads created by the same process can operate on the mutex. Using `PTHREAD_PROCESS_PRIVATE` results in the same behavior as with the `USYNC_THREAD` flag in the original Solaris threads `cond_init()` call, which is that of a local condition variable. `PTHREAD_PROCESS_SHARED` is equivalent to a global condition variable.

```
Prototype:
int pthread_condattr_setpshared(pthread_condattr_t *cattr,
    int pshared);

#include <pthread.h>

pthread_condattr_t cattr;
int ret;

/* all processes */
ret = pthread_condattr_setpshared(&cattr, PTHREAD_PROCESS_SHARED);

/* within a process */
ret = pthread_condattr_setpshared(&cattr, PTHREAD_PROCESS_PRIVATE);
```

Return Values

`pthread_condattr_setpshared()` returns zero after completing successfully. Any other returned value indicates that an error occurred. If the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

   The value of *cattr* is invalid, or the *pshared* value is invalid.

Get the Scope of a Condition Variable

pthread_condattr_getpshared(3T)

`pthread_condattr_getpshared`(3T) gets the current value of *pshared* for the attribute object *cattr*. The value is either `PTHREAD_PROCESS_SHARED` or `PTHREAD_PROCESS_PRIVATE`.

```
Prototype:
int pthread_condattr_getpshared(const pthread_condattr_t *cattr,
    int *pshared);

#include <pthread.h>

pthread_condattr_t cattr;
int pshared;
int ret;

/* get pshared value of condition variable */
ret = pthread_condattr_getpshared(&cattr, &pshared);
```

Return Values

`pthread_condattr_getpshared( )` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

    The value of *cattr* is invalid.

Using Condition Variables

This section explains using condition variables. Table 4–6 lists the functions that are available.

TABLE 4–6   Condition Variables Functions

Operation	Destination Discussion
Initialize a condition variable	"pthread_cond_init(3T)" on page 111
Block on a condition variable	"pthread_cond_wait(3T)" on page 112

TABLE 4–6   Condition Variables Functions   *(continued)*

Operation	Destination Discussion
Unblock a specific thread	"pthread_cond_signal(3T)" on page 114
Block until a specified event	"pthread_cond_timedwait(3T)" on page 115
Unblock all threads	"pthread_cond_broadcast(3T)" on page 116
Destroy condition variable state	"pthread_cond_destroy(3T)" on page 118

Initialize a Condition Variable

pthread_cond_init(3T)

Use `pthread_cond_init`(3T) to initialize the condition variable pointed at by *cv* to its default value (*cattr* is NULL), or to specify condition variable attributes that are already set with `pthread_condattr_init( )`. The effect of *cattr* being NULL is the same as passing the address of a default condition variable attribute object, but without the memory overhead. (For Solaris threads, see "cond_init(3T)" on page 224.)

```
Prototype:
int pthread_cond_init(pthread_cond_t *cv,
    const pthread_condattr_t *cattr);

#include <pthread.h>

pthread_cond_t cv;
pthread_condattr_t cattr;
int ret;

/* initialize a condition variable to its default value */
ret = pthread_cond_init(&cv, NULL);

/* initialize a condition variable */
ret = pthread_cond_init(&cv, &cattr);
```

Statically defined condition variables can be initialized directly to have default attributes with the macro PTHREAD_COND_INITIALIZER. This has the same effect

as dynamically allocating `pthread_cond_init()` with null attributes. No error checking is done.

Multiple threads must not simultaneously initialize or reinitialize the same condition variable. If a condition variable is reinitialized or destroyed, the application must be sure the condition variable is not in use.

Return Values

`pthread_cond_init()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

  The value specified by *cattr* is invalid.

EBUSY

  The condition variable is being used.

EAGAIN

  The necessary resources are not available.

ENOMEM

  There is not enough memory to initialize the condition variable.

Block on a Condition Variable

pthread_cond_wait(3T)

Use `pthread_cond_wait`(3T) to atomically release the mutex pointed to by *mp* and to cause the calling thread to block on the condition variable pointed to by *cv*. (For Solaris threads, see "cond_wait(3T)" on page 225.)

```
Prototype:
int pthread_cond_wait(pthread_cond_t *cv,pthread_mutex_t *mutex);

#include <pthread.h>

pthread_cond_t cv;
pthread_mutex_t mp;
int ret;

/* wait on condition variable */
```

ret = pthread_cond_wait(&*cv*, &*mp*);

The blocked thread can be awakened by a pthread_cond_signal(), a
pthread_cond_broadcast(), or when interrupted by delivery of a signal.

Any change in the value of a condition associated with the condition variable cannot
be inferred by the return of pthread_cond_wait(), and any such condition must
be reevaluated.

The pthread_cond_wait() routine always returns with the mutex locked and
owned by the calling thread, even when returning an error.

This function blocks until the condition is signaled. It atomically releases the
associated mutex lock before blocking, and atomically acquires it again before
returning.

In typical use, a condition expression is evaluated under the protection of a mutex
lock. When the condition expression is false, the thread blocks on the condition
variable. The condition variable is then signaled by another thread when it changes
the condition value. This causes one or all of the threads waiting on the condition to
unblock and to try to acquire the mutex lock again.

Because the condition can change before an awakened thread returns from
pthread_cond_wait(), the condition that caused the wait must be retested before
the mutex lock is acquired. The recommended test method is to write the condition
check as a while() loop that calls pthread_cond_wait().

```
pthread_mutex_lock();
    while(condition_is_false)
        pthread_cond_wait();
pthread_mutex_unlock();
```

No specific order of acquisition is guaranteed when more than one thread blocks on
the condition variable.

Note - pthread_cond_wait() is a cancellation point. If a cancel is pending and
the calling thread has cancellation enabled, the thread terminates and begins
executing its cleanup handlers while continuing to hold the lock.

Return Values

pthread_cond_wait() returns zero after completing successfully. Any other
returned value indicates that an error occurred. When the following condition occurs,
the function fails and returns the corresponding value.

EINVAL

  The value specified by *cv* or *mp* is invalid.

Unblock a Specific Thread

pthread_cond_signal(3T)

Use `pthread_cond_signal`(3T) to unblock one thread that is blocked on the condition variable pointed to by *cv*. (For Solaris threads, see "cond_signal(3T)" on page 226.)

```
Prototype:
int pthread_cond_signal(pthread_cond_t *cv);

#include <pthread.h>

pthread_cond_t cv;
int ret;

/* one condition variable is signaled */
ret = pthread_cond_signal(&cv);
```

Call `pthread_cond_signal()` under the protection of the same mutex used with the condition variable being signaled. Otherwise, the condition variable could be signaled between the test of the associated condition and blocking in `pthread_cond_wait()`, which can cause an infinite wait.

The scheduling policy determines the order in which blocked threads are awakened. For `SCHED_OTHER`, threads are awakened in priority order.

When no threads are blocked on the condition variable, calling `pthread_cond_signal()` has no effect.

Return Values

`pthread_cond_signal()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

> *cv* points to an illegal address.

Code Example 4–8 shows how to use `pthread_cond_wait()` and `pthread_cond_signal()`.

CODE EXAMPLE 4–8   Using `pthread_cond_wait()` and `pthread_cond_signal()`

```
pthread_mutex_t count_lock;
pthread_cond_t count_nonzero;
unsigned count;

decrement_count()
```

```
{
    pthread_mutex_lock(&count_lock);
    while (count == 0)
        pthread_cond_wait(&count_nonzero, &count_lock);
    count = count - 1;
    pthread_mutex_unlock(&count_lock);
}

increment_count()
{
    pthread_mutex_lock(&count_lock);
    if (count == 0)
        pthread_cond_signal(&count_nonzero);
    count = count + 1;
    pthread_mutex_unlock(&count_lock);
}
```

Block Until a Specified Event

pthread_cond_timedwait(3T)

```
Prototype:
int pthread_cond_timedwait(pthread_cond_t *cv,
    pthread_mutex_t *mp, const struct timespec *abstime);

#include <pthread.h>
#include <time.h>

pthread_cond_t cv;
pthread_mutex_t mp;
timestruct_t abstime;
int ret;

/* wait on condition variable */
ret = pthread_cond_timedwait(&cv, &mp, &abstime);
```

Use `pthread_cond_timedwait`(3T) as you would use `pthread_cond_wait()`,
except that `pthread_cond_timedwait()` does not block past the time of day
specified by *abstime*. `pthread_cond_timedwait()` always returns with the mutex
locked and owned by the calling thread, even when it is returning an error. (For
Solaris threads, see "cond_timedwait(3T)" on page 226.)

The `pthread_cond_timedwait()` function blocks until the condition is signaled
or until the time of day, specified by the last argument, has passed.

Note - `pthread_cond_timedwait()` is also a cancellation point.

Return Values

`pthread_cond_timedwait()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When either of the following conditions occurs, the function fails and returns the corresponding value.

`EINVAL`

> *cv* or *abstime* points to an illegal address.

`ETIMEDOUT`

> The time specified by *abstime* has passed.

The timeout is specified as a time of day so that the condition can be retested efficiently without recomputing the value, as shown in Code Example 4–9.

CODE EXAMPLE 4–9   Timed Condition Wait

```
pthread_timestruc_t to;
pthread_mutex_t m;
pthread_cond_t c;
...
pthread_mutex_lock(&m);
to.tv_sec = time(NULL) + TIMEOUT;
to.tv_nsec = 0;
while (cond == FALSE) {
    err = pthread_cond_timedwait(&c, &m, &to);
    if (err == ETIMEDOUT) {
        /* timeout, do something */
        break;
    }
}
pthread_mutex_unlock(&m);
```

Unblock All Threads

pthread_cond_broadcast(3T)

```
Prototype:
int pthread_cond_broadcast(pthread_cond_t *cv);

#include <pthread.h>

pthread_cond_t cv;
int ret;

/* all condition variables are signaled */
ret = pthread_cond_broadcast(&cv);
```

Use `pthread_cond_broadcast`(3T) to unblock all threads that are blocked on the condition variable pointed to by *cv*, specified by `pthread_cond_wait()`. When no threads are blocked on the condition variable, `pthread_cond_broadcast()` has no effect. (For Solaris threads, see "cond_broadcast(3T)" on page 227.)

Return Values

`pthread_cond_broadcast()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the function fails and returns the corresponding value.

EINVAL

   cv points to an illegal address.

Condition Variable Broadcast Example

Since `pthread_cond_broadcast()` causes all threads blocked on the condition to contend again for the mutex lock, use it with care. For example, use `pthread_cond_broadcast()` to allow threads to contend for varying resource amounts when resources are freed, as shown in Code Example 4–10.

CODE EXAMPLE 4–10   Condition Variable Broadcast

```
pthread_mutex_t rsrc_lock;
pthread_cond_t rsrc_add;
unsigned int resources;

get_resources(int amount)
{
    pthread_mutex_lock(&rsrc_lock);
    while (resources < amount) {
        pthread_cond_wait(&rsrc_add, &rsrc_lock);
    }
    resources -= amount;
    pthread_mutex_unlock(&rsrc_lock);
}

add_resources(int amount)
{
    pthread_mutex_lock(&rsrc_lock);
    resources += amount;
    pthread_cond_broadcast(&rsrc_add);
    pthread_mutex_unlock(&rsrc_lock);
}
```

Note that in `add_resources()` it does not matter whether *resources* is updated first or if `pthread_cond_broadcast()` is called first inside the mutex lock.

Call `pthread_cond_broadcast()` under the protection of the same mutex that is used with the condition variable being signaled. Otherwise, the condition variable could be signaled between the test of the associated condition and blocking in `pthread_cond_wait()`, which can cause an infinite wait.

Destroy Condition Variable State

pthread_cond_destroy(3T)

Use `pthread_cond_destroy`(3T) to destroy any state associated with the condition variable pointed to by *cv*. (For Solaris threads, see "cond_destroy(3T)" on page 225.)

```
Prototype:
int pthread_cond_destroy(pthread_cond_t *cv);

#include <pthread.h>

pthread_cond_t cv;
int ret;

/* Condition variable is destroyed */
ret = pthread_cond_destroy(&cv);
```

Note that the space for storing the condition variable is not freed.

Return Values

`pthread_cond_destroy()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occur, the function fails and returns the corresponding value.

`EINVAL`

    The value specified by *cv* is invalid.

The Lost Wake-Up Problem

Calling `pthread_cond_signal()` or `pthread_cond_broadcast()` when the thread does not hold the mutex lock associated with the condition can lead to *lost wake-up* bugs.

A lost wake-up occurs when:

- A thread calls `pthread_cond_signal()` or `pthread_cond_broadcast()`.

- *And* another thread is between the test of the condition and the call to
  `pthread_cond_wait()`.

- *And* no threads are waiting.

  The signal has no effect, and therefore is lost.

The Producer/Consumer Problem

This problem is one of the small collection of standard, well-known problems in concurrent programming: a finite-size buffer and two classes of threads, producers and consumers, put items into the buffer (producers) and take items out of the buffer (consumers).

A producer must wait until the buffer has space before it can put something in, and a consumer must wait until something is in the buffer before it can take something out.

A condition variable represents a queue of threads waiting for some condition to be signaled.

Code Example 4–11 has two such queues, one (*less*) for producers waiting for a slot in the buffer, and the other (*more*) for consumers waiting for a buffer slot containing information. The example also has a mutex, as the data structure describing the buffer must be accessed by only one thread at a time.

CODE EXAMPLE 4–11   The Producer/Consumer Problem and Condition Variables

```
typedef struct {
    char buf[BSIZE];
    int occupied;
    int nextin;
    int nextout;
    pthread_mutex_t mutex;
    pthread_cond_t more;
    pthread_cond_t less;
} buffer_t;

buffer_t buffer;
```

As Code Example 4–12 shows, the producer thread acquires the mutex protecting the `buffer` data structure and then makes certain that space is available for the item being produced. If not, it calls `pthread_cond_wait()`, which causes it to join the queue of threads waiting for the condition *less*, representing *there is room in the buffer*, to be signaled.

At the same time, as part of the call to `pthread_cond_wait()`, the thread releases its lock on the mutex. The waiting producer threads depend on consumer threads to signal when the condition is true (as shown in Code Example 4–12). When the condition is signaled, the first thread waiting on *less* is awakened. However, before the thread can return from `pthread_cond_wait()`, it must acquire the lock on the mutex again.

This ensures that it again has mutually exclusive access to the buffer data structure. The thread then must check that there really is room available in the buffer; if so, it puts its item into the next available slot.

At the same time, consumer threads might be waiting for items to appear in the buffer. These threads are waiting on the condition variable *more*. A producer thread, having just deposited something in the buffer, calls pthread_cond_signal() to wake up the next waiting consumer. (If there are no waiting consumers, this call has no effect.)

Finally, the producer thread unlocks the mutex, allowing other threads to operate on the buffer data structure.

CODE EXAMPLE 4–12   The Producer/Consumer Problem—the Producer

```
void producer(buffer_t *b, char item)
{
    pthread_mutex_lock(&b->mutex);

    while (b->occupied >= BSIZE)
        pthread_cond_wait(&b->less, &b->mutex);

    assert(b->occupied < BSIZE);

    b->buf[b->nextin++] = item;

    b->nextin %= BSIZE;
    b->occupied++;

    /* now: either b->occupied < BSIZE and b->nextin is the index
       of the next empty slot in the buffer, or
       b->occupied == BSIZE and b->nextin is the index of the
       next (occupied) slot that will be emptied by a consumer
       (such as b->nextin == b->nextout) */

    pthread_cond_signal(&b->more);

    pthread_mutex_unlock(&b->mutex);
}
```

Note the use of the assert() statement; unless the code is compiled with NDEBUG defined, assert() does nothing when its argument evaluates to true (that is, nonzero), but causes the program to abort if the argument evaluates to false (zero). Such assertions are especially useful in multithreaded programs—they immediately point out runtime problems if they fail, and they have the additional effect of being useful comments.

The comment that begins /* now: either b->occupied ... could better be expressed as an assertion, but it is too complicated as a Boolean-valued expression and so is given in English.

Both the assertion and the comments are examples of invariants. These are logical statements that should not be falsified by the execution of the program, except during brief moments when a thread is modifying some of the program variables

mentioned in the invariant. (An assertion, of course, should be true whenever any thread executes it.)

Using invariants is an extremely useful technique. Even if they are not stated in the program text, think in terms of invariants when you analyze a program.

The invariant in the producer code that is expressed as a comment is always true whenever a thread is in the part of the code where the comment appears. If you move this comment to just after the mutex_unlock( ), this does not necessarily remain true. If you move this comment to just after the assert( ), this is still true.

The point is that this invariant expresses a property that is true at all times, except when either a producer or a consumer is changing the state of the buffer. While a thread is operating on the buffer (under the protection of a mutex), it might temporarily falsify the invariant. However, once the thread is finished, the invariant should be true again.

Code Example 4–13 shows the code for the consumer. Its flow is symmetric with that of the producer.

CODE EXAMPLE 4–13   The Producer/Consumer Problem—the Consumer

```
char consumer(buffer_t *b)
{
    char item;
    pthread_mutex_lock(&b->mutex);
    while(b->occupied <= 0)
        pthread_cond_wait(&b->more, &b->mutex);

    assert(b->occupied > 0);

    item = b->buf[b->nextout++];
    b->nextout %= BSIZE;
    b->occupied--;

    /* now: either b->occupied > 0 and b->nextout is the index
       of the next occupied slot in the buffer, or
       b->occupied == 0 and b->nextout is the index of the next
       (empty) slot that will be filled by a producer (such as
       b->nextout == b->nextin) */

    pthread_cond_signal(&b->less);
    pthread_mutex_unlock(&b->mutex);

    return(item);
}
```

Semaphores

Semaphores are a programming construct designed by E. W. Dijkstra in the late 1960s. Dijkstra's model was the operation of railroads: consider a stretch of railroad in which there is a single track over which only one train at a time is allowed.

Guarding this track is a semaphore. A train must wait before entering the single track until the semaphore is in a state that permits travel. When the train enters the track, the semaphore changes state to prevent other trains from entering the track. A train that is leaving this section of track must again change the state of the semaphore to allow another train to enter.

In the computer version, a semaphore appears to be a simple integer. A thread waits for permission to proceed and then signals that it has proceeded by performing a `P` operation on the semaphore.

The semantics of the operation are such that the thread must wait until the semaphore's value is positive, then change the semaphore's value by subtracting one from it. When it is finished, the thread performs a `V` operation, which changes the semaphore's value by adding one to it. It is crucial that these operations take place atomically—they cannot be subdivided into pieces between which other actions on the semaphore can take place. In the `P` operation, the semaphore's value must be positive just before it is decremented (resulting in a value that is guaranteed to be nonnegative and one less than what it was before it was decremented).

In both `P` and `V` operations, the arithmetic must take place without interference. If two `V` operations are performed simultaneously on the same semaphore, the net effect should be that the semaphore's new value is two greater than it was.

The mnemonic significance of `P` and `V` is unclear to most of the world, as Dijkstra is Dutch. However, in the interest of true scholarship: `P` stands for prolagen, a made-up word derived from proberen te verlagen, which means *try to decrease*. `V` stands for verhogen, which means *increase*. This is discussed in one of Dijkstra's technical notes, EWD 74.

`sem_wait`(3R) and `sem_post`(3R) correspond to Dijkstra's `P` and `V` operations. `sem_trywait`(3R) is a conditional form of the `P` operation: if the calling thread cannot decrement the value of the semaphore without waiting, the call returns immediately with a nonzero value.

There are two basic sorts of semaphores: binary semaphores, which never take on values other than zero or one, and counting semaphores, which can take on arbitrary nonnegative values. A binary semaphore is logically just like a mutex.

However, although it is not enforced, mutexes should be unlocked only by the thread holding the lock. There is no notion of "the thread holding the semaphore," so any thread can perform a `V` (or sem_post(3R)) operation.

Counting semaphores are about as powerful as conditional variables (used in conjunction with mutexes). In many cases, the code might be simpler when it is implemented with counting semaphores rather than with condition variables (as shown in the next few examples).

However, when a mutex is used with condition variables, there is an implied bracketing—it is clear which part of the program is being protected. This is not necessarily the case for a semaphore, which might be called the *go to* of concurrent programming—it is powerful but too easy to use in an unstructured, indeterminate way.

Counting Semaphores

Conceptually, a semaphore is a nonnegative integer count. Semaphores are typically used to coordinate access to resources, with the semaphore count initialized to the number of free resources. Threads then atomically increment the count when resources are added and atomically decrement the count when resources are removed.

When the semaphore count becomes zero, indicating that no more resources are present, threads trying to decrement the semaphore block wait until the count becomes greater than zero.

TABLE 4–7   Routines for Semaphores

Operation	Destination Discussion
Initialize a semaphore	"sem_init(3R)" on page 124
Increment a semaphore	"sem_post(3R)" on page 126
Block on a semaphore count	"sem_wait(3R)" on page 126
Decrement a semaphore count	"sem_trywait(3R)" on page 127
Destroy the semaphore state	"sem_destroy(3R)" on page 128

Because semaphores need not be acquired and released by the same thread, they can be used for asynchronous event notification (such as in signal handlers). And, because semaphores contain state, they can be used asynchronously without

acquiring a mutex lock as is required by condition variables. However, semaphores are not as efficient as mutex locks.

By default, there is no defined order of unblocking if multiple threads are waiting for a semaphore.

Semaphores must be initialized before use, but they do not have attributes.

Initialize a Semaphore

sem_init(3R)

```
Prototype:
int sem_init(sem_t *sem, int pshared, unsigned int value);

#include <semaphore.h>

sem_t sem;
int pshared;
int ret;
int value;

/* initialize a private semaphore */
pshared = 0;
value = 1;
ret = sem_init(&sem, pshared, value);
```

Use sem_init(3R) to initialize the semaphore variable pointed to by *sem* to *value* amount. If the value of pshared is zero, then the semaphore cannot be shared between processes. If the value of pshared is nonzero, then the semaphore can be shared between processes. (For Solaris threads, see "sema_init(3T)" on page 227.)

Multiple threads must not initialize the same semaphore.

A semaphore must not be reinitialized while other threads might be using it.

Return Values

sem_init() returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

   The value argument exceeds SEM_VALUE_MAX.

ENOSPC

A resource required to initialize the semaphore has been exhausted. The limit on semaphores `SEM_NSEMS_MAX` has been reached.

`EPERM`

The process lacks the appropriate privileges to initialize the semaphore.

Initializing Semaphores With Intraprocess Scope

When *pshared* is 0, the semaphore can be used by all the threads in this process only.

```
#include <semaphore.h>

sem_t sem;
int ret;
int count = 4;

/* to be used within this process only */
ret = sem_init(&sem, 0, count);
```

Initializing Semaphores With Interprocess Scope

When *pshared* is nonzero, the semaphore can be shared by other processes.

```
#include <semaphore.h>

sem_t sem;
int ret;
int count = 4;

/* to be shared among processes */
ret = sem_init(&sem, 1, count);
```

Named Semaphores

The functions `sem_open(3R)`, `sem_getvalue(3R)`, `sem_close(3R)`, and `sem_unlink(3R)` are available to `open`, `retrieve`, `close`, and `remove` named semaphores. Using `sem_open( )`, you can create a semaphore that has a name defined in the file system name space.

Named semaphores are like process shared semaphores, except that they are referenced with a pathname rather than a *pshared* value.

For more information about named semaphores, see `sem_open(3R)`, `sem_getvalue(3R)`, `sem_close(3R)`, and `sem_unlink(3R)`.

Increment a Semaphore

sem_post(3R)

```
Prototype:
int sem_post(sem_t *sem);
```

```
#include <semaphore.h>
```

```
sem_t sem;
int ret;
```

```
ret = sem_post(&sem); /* semaphore is posted */
```

Use `sem_post`(3R) to atomically increment the semaphore pointed to by *sem*. When any threads are blocked on the semaphore, one of them is unblocked. (For Solaris threads, see "sema_post(3T)" on page 228.)

Return Values

`sem_post()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the function fails and returns the corresponding value.

```
EINVAL
```

sem points to an illegal address.

Block on a Semaphore Count

sem_wait(3R)

```
Prototype:
int sem_wait(sem_t *sem);
```

```
#include <semaphore.h>
```

```
sem_t sem;
int ret;
```

```
ret = sem_wait(&sem); /* wait for semaphore */
```

Use `sem_wait`(3R) to block the calling thread until the count in the semaphore pointed to by *sem* becomes greater than zero, then atomically decrement it.

Return Values

`sem_wait()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

   sem points to an illegal address.

EINTR

   A signal interrupted this function.

Decrement a Semaphore Count

sem_trywait(3R)

```
Prototype:
int sem_trywait(sem_t *sem);

#include <semaphore.h>

sem_t sem;
int ret;

ret = sem_trywait(&sem); /* try to wait for semaphore*/
```

Use `sem_trywait`(3R) to try to atomically decrement the count in the semaphore pointed to by *sem* when the count is greater than zero. This function is a nonblocking version of `sem_wait()`; that is it returns immediately if unsuccessful.

Return Values

`sem_trywait()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

   sem points to an illegal address.

EINTR

   A signal interrupted this function.

EAGAIN

The semaphore was already locked, so it cannot be immediately locked by the `sem_trywait()` operation.

Destroy the Semaphore State

sem_destroy(3R)

```
Prototype:
int sem_destroy(sem_t *sem);

#include <semaphore.h>

sem_t sem;
int ret;

ret = sem_destroy(&sem); /* the semaphore is destroyed */
```

Use `sem_destroy`(3R) to destroy any state associated with the semaphore pointed to by *sem*. The space for storing the semaphore is not freed. (For Solaris threads, see "sema_destroy(3T)" on page 229.)

Return Values

`sem_destroy()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, the function fails and returns the corresponding value.

`EINVAL`

   sem points to an illegal address.

The Producer/Consumer Problem, Using Semaphores

The data structure in Code Example 4–14 is similar to that used for the condition variables example (see Code Example 4–11). Two semaphores represent the number of full and empty buffers and ensure that producers wait until there are empty buffers and that consumers wait until there are full buffers.

CODE EXAMPLE 4–14   The Producer/Consumer Problem With Semaphores

```
typedef struct {
    char buf[BSIZE];
```

```
        sem_t occupied;
        sem_t empty;
        int nextin;
        int nextout;
        sem_t pmut;
        sem_t cmut;
} buffer_t;

buffer_t buffer;

sem_init(&buffer.occupied, 0, 0);

sem_init(&buffer.empty,0, BSIZE);
sem_init(&buffer.pmut, 0, 1);
sem_init(&buffer.cmut, 0, 1);
buffer.nextin = buffer.nextout = 0;
```

Another pair of (binary) semaphores plays the same role as mutexes, controlling access to the buffer when there are multiple producers and multiple empty buffer slots, and when there are multiple consumers and multiple full buffer slots. Mutexes would work better here, but would not provide as good an example of semaphore use.

CODE EXAMPLE 4–15   The Producer/Consumer Problem—the Producer

```
void producer(buffer_t *b, char item) {
    sem_wait(&b->empty);

    sem_wait(&b->pmut);

    b->buf[b->nextin] = item;
    b->nextin++;
    b->nextin %= BSIZE;

    sem_post(&b->pmut);

    sem_post(&b->occupied);
}
```

CODE EXAMPLE 4–16   The Producer/Consumer Problem—the Consumer

```
char consumer(buffer_t *b) {
    char item;

    sem_wait(&b->occupied);

    sem_wait(&b->cmut);

    item = b->buf[b->nextout];
    b->nextout++;
    b->nextout %= BSIZE;

    sem_post(&b->cmut);

    sem_post(&b->empty);
```

Programming with Synchronization Objects   **129**

```
        return(item);
}
```

Read-Write Lock Attributes

Read-write locks permit concurrent reads and exclusive writes to a protected shared resource. The read-write lock is a single entity that can be locked in *read* or *write* mode. To modify a resource, a thread must first acquire the exclusive write lock. An exclusive write lock is not permitted until all read locks have been released.

Database access can be synchronized with a read-write lock. Read-write locks support concurrent reads of database records because the read operation does not change the record's information. When the database is to be updated, the write operation must acquire an exclusive write lock.

To change the default read-write lock attributes, you can declare and initialize an attribute object. Often, the read-write lock attributes are set up in one place at the beginning of the application so they can be located quickly and modified easily. The following table lists the functions discussed in this section that manipulate read-write lock attributes.

See "Similar Synchronization Functions—Read-Write Locks" on page 206 for the Solaris threads implementation of read-write locks.

TABLE 4–8   Routines for Read-Write Lock Attributes

Operation	Destination Discussion
Initialize a read-write lock attribute	"pthread_rwlockattr_init(3T)" on page 131
Destroy a read-write lock attribute	"pthread_rwlockattr_destroy(3T)" on page 131
Set a read-write lock attribute	"pthread_rwlockattr_setpshared(3T)" on page 132
Get a read-write lock attribute	"pthread_rwlockattr_getpshared(3T)" on page 132

Initialize a Read-Write Lock Attribute

pthread_rwlockattr_init(3T)

```
#include <pthread.h>

int pthread_rwlockattr_init(pthread_rwlockattr_t *attr);
```

 pthread_rwlockattr_init(3T) initializes a read-write lock attributes object *attr* with the default value for all of the attributes defined by the implementation.

Results are undefined if pthread_rwlockattr_init is called specifying an already initialized read-write lock attributes object. After a read-write lock attributes object has been used to initialize one or more read-write locks, any function affecting the attributes object (including destruction) does not affect any previously initialized read-write locks.

Return Values

If successful, pthread_rwlockattr_init() returns zero. Otherwise, an error number is returned to indicate the error.

ENOMEM

   Insufficient memory exists to initialize the rwlock attributes object.

Destroy a Read-Write Lock Attribute

pthread_rwlockattr_destroy(3T)

```
#include <pthread.h>

int pthread_rwlockattr_destroy(pthread_rwlockattr_t *attr);
```

 pthread_rwlockattr_destroy(3T) destroys a read-write lock attributes object. The effect of subsequent use of the object is undefined until the object is re-initialized by another call to pthread_rwlockattr_init() An implementation can cause pthread_rwlockattr_destroy() to set the object referenced by *attr* to an invalid value.

Return Values

If successful, pthread_rwlockattr_destroy() returns zero. Otherwise, an error number is returned to indicate the error.

EINVAL

The value specified by *attr* is invalid.

Set a Read-Write Lock Attribute

pthread_rwlockattr_setpshared(3T)

```
#include <pthread.h>

int pthread_rwlockattr_setpshared(pthread_rwlockattr_t  *attr, int  pshared);
```

`pthread_rwlockattr_setpshared`(3T) sets the process-shared read-write lock attribute.

PTHREAD_PROCESS_SHARED

Permits a read-write lock to be operated on by any thread that has access to the memory where the read-write lock is allocated, even if the read-write lock is allocated in memory that is shared by multiple processes.

PTHREAD_PROCESS_PRIVATE

The read-write lock will only be operated upon by threads created within the same process as the thread that initialized the read-write lock; if threads of differing processes attempt to operate on such a read-write lock, the behavior is undefined. The default value of the process-shared attribute is PTHREAD_PROCESS_PRIVATE.

Return Value

If successful, `pthread_rwlockattr_setpshared()` returns zero. Otherwise, an error number is returned to indicate the error.

EINVAL

The value specified by *attr* or *pshared* is invalid.

Get a Read-Write Lock Attribute

pthread_rwlockattr_getpshared(3T)

```
#include <pthread.h>
```

```
int pthread_rwlockattr_getpshared(const pthread_rwlockattr_t  *attr, int *pshared);
```

pthread_rwlockattr_getpshared(3T) gets the process-shared read-write lock
attribute.

pthread_rwlockattr_getpshared() obtains the value of the process-shared
attribute from the initialized attributes object referenced by *attr*.

Return Value

If successful, pthread_rwlockattr_getpshared() returns zero. Otherwise, an
error number is returned to indicate the error.

EINVAL

 The value specified by *attr* or *pshared* is invalid.

Using Read-Write Locks

After the attributes for a read-write lock are configured, you initialize the read-write
lock itself. The following functions are used to initialize or destroy, lock or unlock, or
try to lock a read-write lock. The following table lists the functions discussed in this
section that manipulate read-write locks.

TABLE 4–9   Routines that Manipulate Read-Write Locks

Operation	Destination Discussion
Initialize a read-write lock	"pthread_rwlock_init(3T)" on page 134
Read lock on read-write lock	"pthread_rwlock_rdlock(3T)" on page 135
Read lock with a nonblocking read-write lock	"pthread_rwlock_tryrdlock(3T)" on page 136
Write lock on read-write lock	"pthread_rwlock_wrlock(3T)" on page 136
Write lock with a nonblocking read-write lock	"pthread_rwlock_trywrlock(3T)" on page 137

TABLE 4–9   Routines that Manipulate Read-Write Locks   *(continued)*

Operation	Destination Discussion
Unlock a read-write lock	"pthread_rwlock_unlock(3T)" on page 138
Destroy a read-write lock	"pthread_rwlock_destroy(3T)" on page 139

Initialize a Read-Write Lock

pthread_rwlock_init(3T)

```
#include <pthread.h>

int pthread_rwlock_init(pthread_rwlock_t *rwlock, const pthread_rwlockattr_t *attr);

pthread_rwlock_t  rwlock = PTHREAD_RWLOCK_INITIALIZER;
```

Use pthread_rwlock_init(3T) to initialize the read-write lock referenced by *rwlock* with the attributes referenced by *attr*. If *attr* is NULL, the default read-write lock attributes are used; the effect is the same as passing the address of a default read-write lock attributes object. Once initialized, the lock can be used any number of times without being re-initialized. On successful initialization, the state of the read-write lock becomes initialized and unlocked. Results are undefined if pthread_rwlock_init() is called specifying an already initialized read-write lock. Results are undefined if a read-write lock is used without first being initialized. (For Solaris threads, see "rwlock_init(3T)" on page 206.)

In cases where default read-write lock attributes are appropriate, the macro PTHREAD_RWLOCK_INITIALIZER can be used to initialize read-write locks that are statically allocated. The effect is equivalent to dynamic initialization by a call to pthread_rwlock_init() with the parameter *attr* specified as NULL, except that no error checks are performed.

Return Value

If successful, pthread_rwlock_init() returns zero. Otherwise, an error number is returned to indicate the error.

If pthread_rwlock_init() fails, *rwlock* is not initialized and the contents of *rwlock* are undefined.

```
EINVAL
```

The value specified by *attr* or *rwlock* is invalid.

Read Lock on Read-Write Lock

pthread_rwlock_rdlock(3T)

```
#include <pthread.h>

int  pthread_rwlock_rdlock(pthread_rwlock_t *rwlock );
```

 pthread_rwlock_rdlock(3T) applies a read lock to the read-write lock referenced by *rwlock*. The calling thread acquires the read lock if a writer does not hold the lock and there are no writers blocked on the lock. It is unspecified whether the calling thread acquires the lock when a writer does not hold the lock and there are writers waiting for the lock. If a writer holds the lock, the calling thread will not acquire the read lock. If the read lock is not acquired, the calling thread blocks (that is, it does not return from the pthread_rwlock_rdlock()) until it can acquire the lock. Results are undefined if the calling thread holds a write lock on *rwlock* at the time the call is made.

Implementations are allowed to favor writers over readers to avoid writer starvation. (For instance, the Solaris threads implementation favors writers over readers. See "rw_rdlock(3T)" on page 208.)

A thread can hold multiple concurrent read locks on *rwlock* (that is, successfully call pthread_rwlock_rdlock() n times) If so, the thread must perform matching unlocks (that is, it must call pthread_rwlock_unlock() *n* times).

Results are undefined if pthread_rwlock_rdlock() is called with an uninitialized read-write lock.

If a signal is delivered to a thread waiting for a read-write lock for reading, on return from the signal handler the thread resumes waiting for the read-write lock for reading as if it was not interrupted.

Return Value

If successful, pthread_rwlock_rdlock() returns zero. Otherwise, an error number is returned to indicate the error.

```
EINVAL
```

The value specified by *attr* or *rwlock* is invalid.

Read Lock With a Nonblocking Read-Write Lock

pthread_rwlock_tryrdlock(3T)

```
#include <pthread.h>

int pthread_rwlock_tryrdlock(pthread_rwlock_t *rwlock);
```

`pthread_rwlock_tryrdlock`(3T) applies a read lock as in
`pthread_rwlock_rdlock()` with the exception that the function fails if any
thread holds a write lock on *rwlock* or there are writers blocked on *rwlock*. (For
Solaris threads, see "rw_tryrdlock(3T)" on page 208.)

Return Value

`pthread_rwlock_tryrdlock()` returns zero if the lock for reading on the
read-write lock object referenced by *rwlock* is acquired. Otherwise an error number is
returned to indicate the error.

```
EBUSY
```

   The read-write lock could not be acquired for reading because a writer holds the
   lock or was blocked on it.

Write Lock on Read-Write Lock

pthread_rwlock_wrlock(3T)

```
#include <pthread.h>

int  pthread_rwlock_wrlock(pthread_rwlock_t *rwlock );
```

`pthread_rwlock_wrlock`(3T) applies a write lock to the read-write lock
referenced by *rwlock*. The calling thread acquires the write lock if no other thread
(reader or writer) holds the read-write lock *rwlock*. Otherwise, the thread blocks (that
is, does not return from the `pthread_rwlock_wrlock()` call) until it can acquire
the lock. Results are undefined if the calling thread holds the read-write lock
(whether a read or write lock) at the time the call is made.

Implementations are allowed to favor writers over readers to avoid writer starvation.
(For instance, the Solaris threads implementation favors writers over readers. See
"rw_wrlock(3T)" on page 209.)

Results are undefined if `pthread_rwlock_wrlock()` is called with an
uninitialized read-write lock.

If a signal is delivered to a thread waiting for a read-write lock for writing, upon return from the signal handler the thread resumes waiting for the read-write lock for writing as if it was not interrupted.

Return Value

`pthread_rwlock_rwlock()` returns zero if the lock for writing on the read-write lock object referenced by *rwlock* is acquired. Otherwise an error number is returned to indicate the error.

Write Lock With a Nonblocking Read-Write Lock

pthread_rwlock_trywrlock(3T)

```
#include <pthread.h>

int pthread_rwlock_trywrlock(pthread_rwlock_t  *rwlock);
```

`pthread_rwlock_trywrlock`(3T) applies a write lock like `pthread_rwlock_wrlock()`, with the exception that the function fails if any thread currently holds *rwlock* (for reading or writing). (For Solaris threads, see "rw_trywrlock(3T)" on page 210.)

Results are undefined if `pthread_rwlock_trywrlock()` is called with an uninitialized read-write lock.

If a signal is delivered to a thread waiting for a read-write lock for writing, on return from the signal handler the thread resumes waiting for the read-write lock for writing as if it was not interrupted.

Return Value

If successful, `pthread_rwlock_trywrlock()` returns zero if the lock for writing on the read-write lock object referenced by *rwlock* is acquired. Otherwise, an error number is returned to indicate the error.

EBUSY

  The read-write lock could not be acquired for writing because it is already locked for reading or writing.

Unlock a Read-Write Lock

pthread_rwlock_unlock(3T)

```
#include <pthread.h>
```

`pthread_rwlock_unlock`(3T) releases a lock held on the read-write lock object referenced by *rwlock*. Results are undefined if the read-write lock *rwlock* is not held by the calling thread. (For Solaris threads, see "rw_unlock(3T)" on page 210.)

If `pthread_rwlock_unlock` is called to release a read lock from the read-write lock object and there are other read locks currently held on this read-write lock object, the read-write lock object remains in the read locked state. If `pthread_rwlock_unlock()` releases the calling thread's last read lock on this read-write lock object, then the calling thread is no longer one of the owners of the object. If `pthread_rwlock_unlock()` releases the last read lock for this read-write lock object, the read-write lock object will be put in the unlocked state with no owners.

If `pthread_rwlock_unlock()` is called to release a write lock for this read-write lock object, the read-write lock object will be put in the unlocked state with no owners.

If the call to the `pthread_rwlock_unlock()` results in the read-write lock object becoming unlocked and there are multiple threads waiting to acquire the read-write lock object for writing, the scheduling policy is used to determine which thread acquires the read-write lock object for writing. If there are multiple threads waiting to acquire the read-write lock object for reading, the scheduling policy is used to determine the order in which the waiting threads acquire the read-write lock object for reading. If there are multiple threads blocked on *rwlock* for both read locks and write locks, it is unspecified whether the readers acquire the lock first or whether a writer acquires the lock first.

Results are undefined if `pthread_rwlock_unlock()` is called with an uninitialized read-write lock.

Return Value

If successful, `pthread_rwlock_unlock()` returns zero. Otherwise, an error number is returned to indicate the error.

Destroy a Read-Write Lock

pthread_rwlock_destroy(3T)

```
#include <pthread.h>

int pthread_rwlock_destroy(pthread_rwlock_t *rwlock);

pthread_rwlock_t  rwlock = PTHREAD_RWLOCK_INITIALIZER;
```

 `pthread_rwlock_destroy`(3T) destroys the read-write lock object referenced by *rwlock* and releases any resources used by the lock. The effect of subsequent use of the lock is undefined until the lock is re-initialized by another call to `pthread_rwlock_init()` An implementation can cause `pthread_rwlock_destroy()` to set the object referenced by *rwlock* to an invalid value. Results are undefined if `pthread_rwlock_destroy()` is called when any thread holds *rwlock*. Attempting to destroy an uninitialized read-write lock results in undefined behavior. A destroyed read-write lock object can be re-initialized using `pthread_rwlock_init()`; the results of otherwise referencing the read-write lock object after it has been destroyed are undefined. (For Solaris threads, see "rwlock_destroy(3T)" on page 211.)

Return Value

If successful, `pthread_rwlock_destroy()` returns zero. Otherwise, an error number is returned to indicate the error.

`EINVAL`

   The value specified by *attr* or *rwlock* is invalid.

Synchronization Across Process Boundaries

Each of the synchronization primitives can be set up to be used across process boundaries. This is done quite simply by ensuring that the synchronization variable is located in a shared memory segment and by calling the appropriate `init()` routine, after the primitive has been initialized with its shared attribute set as interprocess.

Producer/Consumer Problem Example

Code Example 4–17 shows the producer/consumer problem with the producer and consumer in separate processes. The main routine maps zero-filled memory (that it shares with its child process) into its address space.

A child process is created that runs the consumer. The parent runs the producer.

This example also shows the drivers for the producer and consumer. The `producer_driver()` simply reads characters from `stdin` and calls `producer()`. The `consumer_driver()` gets characters by calling `consumer()` and writes them to `stdout`.

The data structure for Code Example 4–17 is the same as that used for the condition variables example (see Code Example 4–4). Two semaphores represent the number of full and empty buffers and ensure that producers wait until there are empty buffers and that consumers wait until there are full buffers.

CODE EXAMPLE 4–17   Synchronization Across Process Boundaries

```
main() {
    int zfd;
    buffer_t *buffer;
    pthread_mutexattr_t mattr;
    pthread_condattr_t cvattr_less, cvattr_more;

    zfd = open("/dev/zero", O_RDWR);
    buffer = (buffer_t *)mmap(NULL, sizeof(buffer_t),
        PROT_READ|PROT_WRITE, MAP_SHARED, zfd, 0);
    buffer->occupied = buffer->nextin = buffer->nextout = 0;

    pthread_mutex_attr_init(&mattr);
    pthread_mutexattr_setpshared(&mattr,
        PTHREAD_PROCESS_SHARED);

    pthread_mutex_init(&buffer->lock, &mattr);
    pthread_condattr_init(&cvattr_less);
    pthread_condattr_setpshared(&cvattr_less, PTHREAD_PROCESS_SHARED);
    pthread_cond_init(&buffer->less, &cvattr_less);
    pthread_condattr_init(&cvattr_more);
    pthread_condattr_setpshared(&cvattr_more,
        PTHREAD_PROCESS_SHARED);
    pthread_cond_init(&buffer->more, &cvattr_more);

    if (fork() == 0)
        consumer_driver(buffer);
    else
        producer_driver(buffer);
}

void producer_driver(buffer_t *b) {
    int item;

    while (1) {
        item = getchar();
        if (item == EOF) {
            producer(b, '\0');
```

```
                break;
        } else
                producer(b, (char)item);
    }
}

void consumer_driver(buffer_t *b) {
    char item;

    while (1) {
        if ((item = consumer(b)) == '\0')
                break;
        putchar(item);
    }
}
```

Interprocess Locking Without the Threads Library

Although not generally recommended, you can use Solaris threads to do interprocess locking without using the threads library. If this is something you want to do, see the instructions in "Using LWPs Between Processes" on page 230.

Comparing Primitives

The most basic synchronization primitive in threads is the mutual exclusion lock. So, it is the most efficient mechanism in both memory use and execution time. The basic use of a mutual exclusion lock is to serialize access to a resource.

The next most efficient primitive in threads is the condition variable. The basic use of a condition variable is to block on a change of state; that is it provides a thread wait facility. Remember that a mutex lock must be acquired before blocking on a condition variable and must be unlocked after returning from `pthread_cond_wait( )`. The mutex lock must also be held across the change of state that occurs before the corresponding call to `pthread_cond_signal( )`.

The semaphore uses more memory than the condition variable. It is easier to use in some circumstances because a semaphore variable functions on state rather than on control. Unlike a lock, a semaphore does not have an owner. Any thread can increment a semaphore that has blocked.

The read-write lock permits concurrent reads and exclusive writes to a protected resource. The read-write lock is a single entity that can be locked in *read* or *write*

mode. To modify a resource, a thread must first acquire the exclusive write lock. An exclusive write lock is not permitted until all read locks have been released.

Programming With the Operating Environment

This chapter describes how multithreading interacts with the Solaris operating environment and how the operating environment has changed to support multithreading.

- "Process Creation—exec(2)and exit(2) Issues" on page 148
- "Timers, Alarms, and Profiling" on page 148
- "Nonlocal Goto—setjmp(3C) and longjmp(3C)" on page 150

- "Extending Traditional Signals" on page 154
- "I/O Issues" on page 164

Process Creation—Forking Issues

The default handling of the `fork()` function in the Solaris operating environment is somewhat different from the way `fork()` is handled in POSIX threads, although the Solaris operating environment does support both mechanisms.

Table 5–1 compares the differences and similarities of Solaris and pthreads `fork()` handling. When the comparable interface is not available either in POSIX threads or in Solaris threads, the '—' character appears in the table column.

TABLE 5–1 Comparing POSIX and Solaris `fork()` Handling

	Solaris Operating Environment Interface	POSIX Threads Interface
Fork-one model	`fork1(2)`	`fork(2)`
Fork-all model	`fork(2)`	—
Fork safety	—	`pthread_atfork(3T)`

The Fork-One Model

As shown in Table 5–1, the behavior of the pthreads `fork(2)` function is the same as that of the Solaris `fork1(2)` function. Both the pthreads `fork(2)` function and the Solaris `fork1(2)` create a new process, duplicating the complete address space in the child, but duplicating only the calling thread in the child process.

This is useful when the child process immediately calls `exec()`, which is what happens after most calls to `fork()`. In this case, the child process does not need a duplicate of any thread other than the one that called `fork()`.

In the child, do not call any library functions after calling fork() and before calling `exec()` because one of the library functions might use a lock that was held in the parent at the time of the `fork()`. The child process might execute only Async-Signal-Safe operations until one of the `exec()` handlers is called.

The Fork-One Safety Problem and Solution

In addition to all of the usual concerns such as locking shared data, a library should be well behaved with respect to forking a child process when only one thread is running (the one that called `fork()`). The problem is that the sole thread in the child process might try to grab a lock that is held by a thread that wasn't duplicated in the child.

This is not a problem most programs are likely to encounter. Most programs call `exec()` in the child right after the return from `fork()`. However, if the program wishes to carry out some actions in the child before the call to `exec()`, or never calls `exec()`, then the child *could* encounter deadlock scenarios.

Each library writer should provide a safe solution, although not providing a fork-safe library is not a large concern because this condition is rare.

For example, assume that T1 is in the middle of printing something (and so is holding a lock for printf()), when T2 forks a new process. In the child process, if the sole thread (T2) calls printf(), it promptly deadlocks.

The POSIX fork() or Solaris fork1() duplicates only the thread that calls it. (Calling the Solaris fork() duplicates all threads, so this issue does not come up.)

To prevent deadlock, ensure that no such locks are being held at the time of forking. The most obvious way to do this is to have the forking thread acquire all the locks that could possibly be used by the child. Because you cannot do this for locks like those in printf() (because printf() is owned by libc), you must ensure that printf() is not being used at fork() time.

To manage the locks in your library:

- Identify all the locks used by the library.

- Identify the locking order for the locks used by the library. (If a strict locking order is not used, then lock acquisition must be managed carefully.)

- Arrange to acquire those locks at fork time. In Solaris threads this must be done manually, obtaining the locks just before calling fork1(), and releasing them right after.

In the following example, the list of locks used by the library is {L1,...Ln}, and the locking order for these locks is also L1...Ln.

```
mutex_lock(L1);
mutex_lock(L2);
fork1(...);
mutex_unlock(L1);
mutex_unlock(L2);
```

In pthreads, you can add a call to pthread_atfork(f1, f2, f3) in your library's .init() section, where f1(), f2(), f3() are defined as follows:

```
f1() /* This is executed just before the process forks. */
{
 mutex_lock(L1); |
 mutex_lock(...); | -- ordered in lock order
 mutex_lock(Ln); |
 } V

f2() /* This is executed in the child after the process forks. */
 {
 mutex_unlock(L1);
 mutex_unlock(...);
 mutex_unlock(Ln);
 }

f3() /* This is executed in the parent after the process forks. */
 {
 mutex_unlock(L1);
 mutex_unlock(...);
 mutex_unlock(Ln);
 }
```

Another example of deadlock would be a thread in the parent process—other than the one that called Solaris `fork1(2)`—that has locked a mutex. This mutex is copied into the child process in its locked state, but no thread is copied over to unlock the mutex. So, any thread in the child that tries to lock the mutex waits forever.

Virtual Forks–vfork(2)

The standard `vfork(2)` function is unsafe in multithreaded programs. `vfork(2)` is like `fork1(2)` in that only the calling thread is copied in the child process. As in nonthreaded implementations, `vfork()` does not copy the address space for the child process.

Be careful that the thread in the child process does not change memory before it calls `exec(2)`. Remember that `vfork()` gives the parent address space to the child. The parent gets its address space back after the child calls `exec()` or exits. It is important that the child not change the state of the parent.

For example, it is dangerous to create new threads between the call to `vfork()` and the call to `exec()`. This is an issue only if the fork-one model is used, and only if the child does more than just call `exec()`. Most libraries are not fork safe, so use `pthread_atfork()` to implement fork safety.

The Solution—pthread_atfork(3T)

Use `pthread_atfork()` to prevent deadlocks whenever you use the fork-one model.

```
#include <pthread.h>

int pthread_atfork(void (*prepare) (void), void (*parent) (void),
    void (*child) (void) );
```

The `pthread_atfork()` function declares `fork()` handlers that are called before and after `fork()` in the context of the thread that called `fork()`.

- The *prepare* handler is called before `fork()` starts.

- The *parent* handler is called after `fork()` returns in the parent.

- The *child* handler is called after `fork()` returns in the child.

Any one of these can be set to NULL. The order in which successive calls to `pthread_atfork()` are made is significant.

For example, a *prepare* handler could acquire all the mutexes needed, and then the *parent* and *child* handlers could release them. This ensures that all the relevant locks are held by the thread that calls the fork function *before* the process is forked, preventing the deadlock in the child.

Using the fork all model avoids the deadlock problem described in "The Fork-One Safety Problem and Solution" on page 144.

Return Values

`pthread_atfork()` returns a zero when it completes successfully. Any other returned value indicates that an error occurred. If the following condition is detected, pthread_atfork(3T) fails and returns the corresponding value.

ENOMEM

   Insufficient table space exists to record the fork handler addresses.

The Fork-All Model

The Solaris fork(2) function duplicates the address space and all the threads (and LWPs) in the child. This is useful, for example, when the child process never calls `exec(2)` but does use its copy of the parent address space. The fork-all functionality is not available in POSIX threads.

Note that when one thread in a process calls Solaris `fork(2)`, threads that are blocked in an interruptible system call return `EINTR`.

Also, be careful not to create locks that are held by both the parent and child processes. This can happen when locks are allocated in memory that is sharable (that is use `mmap()` with the `MAP_SHARED` flag). Note that this is not a problem if the fork-one model is used.

Choosing the Right Fork

You determine whether `fork()` has a "fork-all" or a "fork-one" semantic in your application by linking with the appropriate library. Linking with −`lthread` gives you the "fork-all" semantic for `fork()`, and linking with −`lpthread` gives the "fork-one" semantic for `fork()` (see Figure 7–1 for an explanation of compiling options).

Cautions for Any Fork

Be careful when using global state after a call to any `fork()` function.

For example, when one thread reads a file serially and another thread in the process successfully calls one of the forks, each process then contains a thread that is reading the file. Because the seek pointer for a file descriptor is shared after a `fork()`, the thread in the parent gets some data while the thread in the child gets the other. This introduces gaps in the sequential read accesses.

Process Creation—exec(2)and exit(2) Issues

Both the `exec(2)` and `exit(2)` system calls work as they do in single-threaded processes except that they destroy all the threads in the address space. Both calls block until all the execution resources (and so all active threads) are destroyed.

When `exec()` rebuilds the process, it creates a single lightweight process (LWP) . The process startup code builds the initial thread. As usual, if the initial thread returns, it calls `exit()` and the process is destroyed.

When all the threads in a process exit, the process exits. A call to any `exec()` function from a process with more than one thread terminates all threads, and loads and executes the new executable image. No destructor functions are called.

Timers, Alarms, and Profiling

The "End of Life" announcements for per-LWP timers (see `timer_create(3R)`) and per-thread alarms (see `alarm(2)` or `setitimer(2)`) were made in the Solaris 2.5 release. Both features are now supplemented with the per-process variants described in this section.

Originally, each LWP had a unique realtime interval timer and alarm that a thread bound to the LWP could use. The timer or alarm delivered one signal to the thread when the timer or alarm expired.

Each LWP also had a virtual time or profile interval timer that a thread bound to the LWP could use. When the interval timer expired, either `SIGVTALRM` or `SIGPROF`, as appropriate, was sent to the LWP that owned the interval timer.

Per-LWP POSIX Timers

In the Solaris 2.3 and 2.4 releases, the `timer_create(3R)` function returned a timer object with a timer ID meaningful only within the calling LWP and with expiration signals delivered to that LWP. Because of this, the only threads that could use the POSIX timer facility were bound threads.

Even with this restricted use, POSIX timers in the Solaris 2.3 and 2.4 releases for multithreaded applications were unreliable about masking the resulting signals and delivering the associated value from the sigvent structure.

Beginning with the Solaris 2.5 release, an application that is compiled defining the macro _POSIX_PER_PROCESS_TIMERS, or with a value greater that `199506L` for the symbol _POSIX_C_SOURCE, can create per-process timers.

Applications compiled with a release before the Solaris 2.5 release, or without the feature test macros, will continue to create per-LWP POSIX timers. In some future release, calls to create per-LWP timers will return per-process timers.

The timer IDs of per-process timers are usable from any LWP, and the expiration signals are generated for the process rather than directed to a specific LWP.

The per-process timers are deleted only by `timer_delete(3R)` or when the process terminates.

Per-Thread Alarms

In the Solaris Operating Environment 2.3 and 2.4 releases, a call to `alarm(2)` or `setitimer(2)` was meaningful only within the calling LWP. Such timers were deleted automatically when the creating LWP terminated. Because of this, the only threads that could use `alarm()` or `setitimer()` were bound threads.

Even with this restricted use, `alarm()` and `setitimer()` timers in Solaris Operating Environment 2.3 and 2.4 multithreaded applications were unreliable about masking the signals from the bound thread that issued these calls. When such masking was not required, then these two system calls worked reliably from bound threads.

With the Solaris Operating Environment 2.5 release, an application linking with −lpthread (POSIX) threads will get per-process delivery of SIGALRM when calling alarm(). The SIGALRM generated by alarm() is generated for the process rather than directed to a specific LWP. Also, the alarm is reset when the process terminates.

Applications compiled with a release before the Solaris Operating Environment 2.5 release, or not linked with −lpthread, will continue to see a per-LWP delivery of signals generated by `alarm()` and `setitimer()`.

In some future release, calls to `alarm()` or to `setitimer()` with the ITIMER_REAL flag will cause the resulting SIGALRM to be sent to the process. For other flags, `setitmer()` will continue to be per-LWP. Flags other than the ITIMER_REAL flag, used by `setitimer()`, will continue to result in the generated signal being delivered to the LWP that issued the call, and so are usable only from bound threads.

Profiling

You can profile each LWP with `profil(2)`, giving each LWP its own buffer, or sharing buffers between LWPs. Profiling data is updated at each clock tick in LWP user time. The profile state is inherited from the creating LWP.

Nonlocal Goto—setjmp(3C) and longjmp(3C)

The scope of `setjmp()` and `longjmp()` is limited to one thread, which is fine most of the time. However, this does mean that a thread that handles a signal can `longjmp()` only when `setjmp()` is performed in the same thread.

Resource Limits

Resource limits are set on the entire process and are determined by adding the resource use of all threads in the process. When a soft resource limit is exceeded, the offending thread is sent the appropriate signal. The sum of the resources used in the process is available through getrusage(3B).

LWPs and Scheduling Classes

As mentioned in the "Scheduling" section of the "Chapter 1, Covering Multithreading Basics", the Solaris pthreads implementation supports only the `SCHED_OTHER` scheduling policy. The others are optional under POSIX.

The POSIX `SCHED_FIFO` and `SCHED_RR` policies can be duplicated or emulated using the standard Solaris mechanisms. These scheduling mechanisms are described in this section.

The Solaris kernel has three classes of scheduling. The highest-priority scheduling class is Realtime (`RT`). The middle-priority scheduling class is `system`. The `system` class cannot be applied to a user process. The lowest-priority scheduling class is timeshare (`TS`), which is also the default class.

Scheduling class is maintained for each LWP. When a process is created, the initial LWP inherits the scheduling class and priority of the creating LWP in the parent process. As more LWPs are created to run unbound threads, they also inherit this scheduling class and priority.

All unbound threads in a process have the same scheduling class and priority. Each scheduling class maps the priority of the LWP it is scheduling to an overall dispatching priority according to the configurable priority of the scheduling class.

Bound threads have the scheduling class and priority of their underlying LWPs. Each bound thread in a process can have a unique scheduling class and priority that is visible to the kernel. Bound threads are scheduled with respect to all other LWPs in the system.

Thread priorities regulate access to LWP resources. By default LWPs are in the timesharing class. For compute-bound multithreading, thread priorities are not very useful. For multithreaded applications that do a lot of synchronization using the MT libraries, thread priorities become more meaningful.

The scheduling class is set by priocntl(2). How you specify the first two arguments determines whether just the calling LWP or all the LWPs of one or more processes are affected. The third argument of `priocntl()` is the command, which can be one of the following.

- `PC_GETCID`. Get the class ID and class attributes for a specific class.

- `PC_GETCLINFO`. Get the class name and class attributes for a specific class.

- `PC_GETPARMS`. Get the class identifier and the class-specific scheduling parameters of a process, an LWP with a process, or a group of processes.

- `PC_SETPARMS`. Set the class identifier and the class-specific scheduling parameters of a process, an LWP with a process, or a group of processes.

Use `priocntl()` only on bound threads. To affect the priority of unbound threads, use pthread_setprio(3T).

Timeshare Scheduling

Timeshare scheduling distributes the processing resource fairly among the LWPs in this scheduling class. Other parts of the kernel can monopolize the processor for short intervals without degrading response time as seen by the user.

The `priocntl(2)` call sets the nice(2) level of one or more processes. The `priocntl()` call also affects the `nice()` level of all the timesharing class LWPs in the process. The `nice()` level ranges from 0 to +20 normally and from -20 to +20 for processes with superuser privilege. The lower the value, the higher the priority.

The dispatch priority of time shared LWPs is calculated from the instantaneous CPU use rate of the LWP and from its `nice()` level. The `nice()` level indicates the relative priority of the LWPs to the timeshare scheduler.

LWPs with a greater `nice()` value get a smaller, but nonzero, share of the total processing. An LWP that has received a larger amount of processing is given lower priority than one that has received little or no processing.

Realtime Scheduling

The Realtime class (RT) can be applied to a whole process or to one or more LWPs in a process. This requires superuser privilege.

Unlike the nice(2) level of the timeshare class, LWPs that are classified Realtime can be assigned priorities either individually or jointly. A priocntl(2) call affects the attributes of all the Realtime LWPs in the process.

The scheduler always dispatches the highest-priority Realtime LWP. It preempts a lower-priority LWP when a higher-priority LWP becomes runnable. A preempted LWP is placed at the head of its level queue.

A Realtime LWP retains control of a processor until it is preempted, it suspends, or its Realtime priority is changed. LWPs in the RT class have absolute priority over processes in the TS class.

A new LWP inherits the scheduling class of the parent process or LWP. An RT class LWP inherits the parent's time slice, whether finite or infinite.

An LWP with a finite time slice runs until it terminates, blocks (for example, to wait for an I/O event), is preempted by a higher-priority runnable Realtime process, or the time slice expires.

An LWP with an infinite time slice ceases execution only when it terminates, blocks, or is preempted.

LWP Scheduling and Thread Binding

The threads library automatically adjusts the number of LWPs in the pool used to run unbound threads. Its objectives are:

- To prevent the program from being blocked by a lack of unblocked LWPs.

  For example, if there are more runnable unbound threads than LWPs and all the active threads block in the kernel in indefinite waits (such as while reading a tty), the process cannot progress until a waiting thread returns.

- To make efficient use of LWPs.

  For example, if the library creates one LWP for each thread, many LWPs will usually be idle and the operating environment is overloaded by the resource requirements of the unused LWPs.

Keep in mind that LWPs are time sliced, not threads. This means that when there is only one LWP, there is no time slicing within the process—threads run on the LWP until they block (through interthread synchronization), are preempted, or terminate.

You can assign priorities to threads with pthread_setprio(3T); lower-priority unbound threads are assigned to LWPs only when no higher-priority unbound threads are available. Bound threads, of course, do not compete for LWPs because

they have their own. Note that the thread priority that is set with
`pthread_setprio()` regulates threads access to LWPs, not to CPUs.

Bind threads to your LWPs to get precise control over whatever is being scheduled. This control is not possible when many unbound threads compete for an LWP.

In particular, a lower-priority unbound thread could be on a higher-priority LWP and running on a CPU, while a higher-priority unbound thread assigned to a lower-priority LWP is not running. In this sense, thread priorities are just a hint about access to CPUs.

Realtime threads are useful for getting a quick response to external stimuli. Consider a thread used for mouse tracking that must respond instantly to mouse clicks. By binding the thread to an LWP, you guarantee that there is an LWP available when it is needed. By assigning the LWP to the Realtime scheduling class, you ensure that the LWP is scheduled quickly in response to mouse clicks.

SIGWAITING—Creating LWPs for Waiting Threads

The library usually ensures that there are enough LWPs in its pool for a program to proceed.

When all the LWPs in the process are blocked in indefinite waits (such as blocked reading from a tty or network), the operating environment sends the new signal, `SIGWAITING`, to the process. This signal is handled by the threads library. When the process contains a thread that is waiting to run, a new LWP is created and the appropriate waiting thread is assigned to it for execution.

The `SIGWAITING` mechanism does not ensure that an additional LWP is created when one or more threads are compute bound and another thread becomes runnable. A compute-bound thread can prevent multiple runnable threads from being started because of a shortage of LWPs.

This can be prevented by calling `thr_setconcurrency`(3T). While using `thr_setconcurrency()` with POSIX threads is not POSIX compliant, its use is recommended to avoid LWP shortages for unbound threads in some computationally intensive situations. (The only way to be *completely* POSIX compliant *and* avoid LWP shortages is to create only `PTHREAD_SCOPE_SYSTEM` bound threads.)

See "Thread Concurrency (Solaris Threads Only)" on page 243 for more information about using the thr_setconcurrency(3T) function.

In Solaris threads, you can also use `THR_NEW_LWP` in calls to `thr_create`(3T) to create another LWP.

Aging LWPs

When the number of active threads is reduced, some of the LWPs in the pool are no longer needed. When there are more LWPs than active threads, the threads library destroys the unneeded LWPs. The library ages LWPs—they are deleted when they are unused for a "long" time; the default is five minutes.

Extending Traditional Signals

The traditional UNIX signal model is extended to threads in a fairly natural way. The key characteristics are that the signal disposition is process-wide, but the signal mask is per-thread. The process-wide disposition of signals is established using the traditional mechanisms (signal(2), sigaction(2), and so on).

When a signal handler is marked SIG_DFL or SIG_IGN, the action on receipt of the signal (exit, core dump, stop, continue, or ignore) is performed on the entire receiving process, affecting all threads in the process. For these signals that don't have handlers, the issue of which thread picks the signal is unimportant, because the action on receipt of the signal is carried out on the whole process. See signal(5) for basic information about signals.

Each thread has its own signal mask. This lets a thread block some signals while it uses memory or another state that is also used by a signal handler. All threads in a process share the set of signal handlers set up by sigaction(2) and its variants.

A thread in one process cannot send a signal to a specific thread in another process. A signal sent by kill(2) or sigsend(2) to a process is handled by any one of the receptive threads in the process.

Unbound threads cannot use alternate signal stacks. A bound thread can use an alternate stack because the state is associated with the execution resource. An alternate stack must be enabled for the signal through sigaction(2), and declared and enabled through signaltstack(2).

An application can have per-thread signal handlers based on the per-process signal handlers. One way is for the process-wide signal handler to use the identifier of the thread handling the signal as an index into a table of per-thread handlers. Note that there is no thread zero.

Signals are divided into two categories: traps and exceptions (synchronously generated signals) and interrupts (asynchronously generated signals).

As in traditional UNIX, if a signal is pending, additional occurrences of that signal have no additional effect—a pending signal is represented by a bit, not by a counter. In other words, signal delivery is idempotent.

As is the case with single-threaded processes, when a thread receives a signal while blocked in a system call, the thread might return early, either with the EINTR error code, or, in the case of I/O calls, with fewer bytes transferred than requested.

Of particular importance to multithreaded programs is the effect of signals on pthread_cond_wait(3T). This call usually returns in response to a pthread_cond_signal(3T) or a pthread_cond_broadcast(3T), but, if the waiting thread receives a traditional UNIX signal, it returns with the error code EINTR. See "Interrupted Waits on Condition Variables (Solaris Threads Only)" on page 162 for more information.

Synchronous Signals

Traps (such as SIGILL, SIGFPE, SIGSEGV) result from something a thread does to itself, such as dividing by zero or explicitly sending itself a signal. A trap is handled only by the thread that caused it. Several threads in a process can generate and handle the same type of trap simultaneously.

Extending the idea of signals to individual threads is easy for synchronous signals—the signal is dealt with by the thread that caused the problem.

However, if the thread has not chosen to deal with the problem, such as by establishing a signal handler with sigaction(2), the handler is invoked on the thread that receives the synchronous signal.

Because such a synchronous signal usually means that something is seriously wrong with the whole process, and not just with a thread, terminating the process is often a good choice.

Asynchronous Signals

Interrupts (such as SIGINT and SIGIO) are asynchronous with any thread and result from some action outside the process. They might be signals sent explicitly by other threads, or they might represent external actions such as a user typing Control-c. Dealing with asynchronous signals is more complicated than dealing with synchronous signals.

An interrupt can be handled by any thread whose signal mask allows it. When more than one thread is able to receive the interrupt, only one is chosen.

When multiple occurrences of the same signal are sent to a process, then each occurrence can be handled by a separate thread, as long as threads are available that do not have it masked. When all threads have the signal masked, then the signal is marked *pending* and the first thread to unmask the signal handles it.

Continuation Semantics

Continuation semantics are the traditional way to deal with signals. The idea is that when a signal handler returns, control resumes where it was at the time of the interruption. This is well suited for asynchronous signals in single-threaded processes, as shown in Code Example 5–1.

This is also used as the exception-handling mechanism in some programming languages, such as PL/1.

CODE EXAMPLE 5–1   Continuation Semantics

```
unsigned int nestcount;

unsigned int A(int i, int j) {
    nestcount++;

    if (i==0)
        return(j+1)
    else if (j==0)
        return(A(i-1, 1));
    else
        return(A(i-1, A(i, j-1)));
}

void sig(int i) {
    printf("nestcount = %d\n", nestcount);
}

main() {
    sigset(SIGINT, sig);
    A(4,4);
}
```

Operations on Signals

pthread_sigsetmask(3T)

pthread_sigsetmask(3T) does for a thread what sigprocmask(2) does for a process—it sets the thread's signal mask. When a new thread is created, its initial mask is inherited from its creator.

The call to sigprocmask() in a multithreaded process is equivalent to a call to pthread_sigsetmask(). See the sigprocmask(2) page for more information.

pthread_kill(3T)

 pthread_kill(3T) is the thread analog of kill(2)—it sends a signal to a specific thread.This, of course, is different from sending a signal to a process. When a signal is sent to a process, the signal can be handled by any thread in the process. A signal sent by pthread_kill() can be handled only by the specified thread.

Note than you can use `pthread_kill()` to send signals only to threads in the current process. This is because the thread identifier (type *thread_t*) is local in scope—it is not possible to name a thread in any process but your own.

Note also that the action taken (handler, `SIG_DFL`, `SIG_IGN`) on receipt of a signal by the target thread is global, as usual. This means, for example, that if you send SIG*XXX* to a thread, and the SIG*XXX* signal disposition for the process is to kill the process, then the whole process is killed when the target thread receives the signal.

sigwait(2)

For multithreaded programs, sigwait(2) is the preferred interface to use, because it deals so well with aysynchronously generated signals.

`sigwait()` causes the calling thread to wait until any signal identified by its set argument is delivered to the thread. While the thread is waiting, signals identified by the set argument are unmasked, but the original mask is restored when the call returns.

All signals identified by the set argument must be blocked on all threads, including the calling thread; otherwise, `sigwait()` might not work correctly.

Use `sigwait()` to separate threads from asynchronous signals. You can create one thread that is listening for asynchronous signals while your other threads are created to block any asynchronous signals that might be set to this process.

New `sigwait()` *Implementations*

Two versions of `sigwait()` are available beginning with the Solaris Operating Environment 2.5 release: the new Solaris Operating Environment 2.5 version, and the POSIX.1c version. New applications and libraries should use the POSIX standard interface, as the Solaris Operating Environment version might not be available in future releases.

Note - The new Solaris Operating Environment 2.5 `sigwait()` does not override the signal's ignore disposition. Applications relying on the older `sigwait(2)` behavior can break unless you install a dummy signal handler to change the disposition from `SIG_IGN` to having a handler, so calls to `sigwait()` for this signal catch it.

The syntax for the two versions of `sigwait()` is shown below.

```
#include <signal.h>

/* the Solaris 2.5 version*/
int sigwait(sigset_t *set);

/* the POSIX.1c version */
int sigwait(const sigset_t *set, int *sig);
```

When the signal is delivered, the POSIX.1c sigwait() clears the pending signal and places the signal number in *sig.* Many threads can call sigwait() at the same time, but only one thread returns for each signal that is received.

With sigwait() you can treat asynchronous signals synchronously—a thread that deals with such signals simply calls sigwait() and returns as soon as a signal arrives. By ensuring that all threads (including the caller of sigwait()) have such signals masked, you can be sure that signals are handled only by the intended handler and that they are handled safely.

By always masking all signals in all threads, and just calling sigwait() as necessary, your application will be much safer for threads that depend on signals.

Usually, you use sigwait() to create one or more threads that wait for signals. Because sigwait() can retrieve even masked signals, be sure to block the signals of interest in all other threads so they are not accidentally delivered.

When the signals arrive, a thread returns from sigwait(), handles the signal, and waits for more signals. The signal-handling thread is not restricted to using Async-Signal-Safe functions and can synchronize with other threads in the usual way. (The Async-Signal-Safe category is defined in "MT Interface Safety Levels" on page 170.)

Note - sigwait() should *never* be used with synchronous signals.

---

sigtimedwait(2)

sigtimedwait(2) is similar to sigwait(2) except that it fails and returns an error when a signal is not received in the indicated amount of time.

Thread-Directed Signals

The UNIX signal mechanism is extended with the idea of thread-directed signals. These are just like ordinary asynchronous signals, except that they are sent to a particular thread instead of to a process.

Waiting for asynchronous signals in a separate thread can be safer and easier than installing a signal handler and processing the signals there.

A better way to deal with asynchronous signals is to treat them synchronously. By calling sigwait(2), discussed in "sigwait(2)" on page 157, a thread can wait until a signal occurs.

CODE EXAMPLE 5–2   Asynchronous Signals and sigwait(2)

```
main() {
    sigset_t set;
    void runA(void);
```

```
        int sig;

        sigemptyset(&set);
        sigaddset(&set, SIGINT);
        pthread_sigsetmask(SIG_BLOCK, &set, NULL);
        pthread_create(NULL, 0, runA, NULL, PTHREAD_DETACHED, NULL);

        while (1) {
            sigwait(&set, &sig);
            printf("nestcount = %d\n", nestcount);
            printf("received signal %d\n", sig);
        }
}

void runA() {
    A(4,4);
    exit(0);
}
```

This example modifies the code of Code Example 5–1: the main routine masks the SIGINT signal, creates a child thread that calls the function A of the previous example, and then issues sigwait() to handle the SIGINT signal.

Note that the signal is masked in the compute thread because the compute thread inherits its signal mask from the main thread. The main thread is protected from SIGINT while, and only while, it is not blocked inside of sigwait().

Also, note that there is never any danger of having system calls interrupted when you use sigwait().

Completion Semantics

Another way to deal with signals is with completion semantics.

Use completion semantics when a signal indicates that something so catastrophic has happened that there is no reason to continue executing the current code block. The signal handler runs instead of the remainder of the block that had the problem. In other words, the signal handler completes the block.

In Code Example 5–3, the block in question is the body of the then part of the if statement. The call to setjmp(3C) saves the current register state of the program in *jbuf* and returns 0, thereby executing the block.

CODE EXAMPLE 5–3   Completion Semantics

```
sigjmp_buf jbuf;
void mult_divide(void) {
    int a, b, c, d;
    void problem();

    sigset(SIGFPE, problem);
    while (1) {
        if (sigsetjmp(&jbuf) == 0) {
```

```
                printf("Three numbers, please:\n");
                scanf("%d %d %d", &a, &b, &c);
                d = a*b/c;
                printf("%d*%d/%d = %d\n", a, b, c, d);
            }
        }
    }

    void problem(int sig) {
        printf("Couldn't deal with them, try again\n");
        siglongjmp(&jbuf, 1);
    }
```

If a SIGFPE (a floating-point exception) occurs, the signal handler is invoked.

The signal handler calls siglongjmp(3C), which restores the register state saved in *jbuf*, causing the program to return from sigsetjmp() again (among the registers saved are the program counter and the stack pointer).

This time, however, sigsetjmp(3C) returns the second argument of siglongjmp(), which is 1. Notice that the block is skipped over, only to be executed during the next iteration of the while loop.

Note that you can use sigsetjmp(3C) and siglongjmp(3C) in multithreaded programs, but be careful that a thread never does a siglongjmp() using the results of another thread's sigsetjmp().

Also, sigsetjmp() and siglongjmp() save and restore the signal mask, but setjmp(3C) and longjmp(3C) do not.

It is best to use sigsetjmp() and siglongjmp() when you work with signal handlers.

Completion semantics are often used to deal with exceptions. In particular, the Sun Ada™ programming language uses this model.

Note - Remember, sigwait(2) should *never* be used with synchronous signals.

Signal Handlers and Async-Signal Safety

A concept similar to thread safety is Async-Signal safety. Async-Signal-Safe operations are guaranteed not to interfere with operations that are being interrupted.

The problem of Async-Signal safety arises when the actions of a signal handler can interfere with the operation that is being interrupted.

For example, suppose a program is in the middle of a call to printf(3S) and a signal occurs whose handler itself calls printf(). In this case, the output of the two printf() statements would be intertwined. To avoid this, the handler should not call printf() itself when printf() might be interrupted by a signal.

This problem cannot be solved by using synchronization primitives because any attempted synchronization between the signal handler and the operation being synchronized would produce immediate deadlock.

Suppose that `printf()` is to protect itself by using a mutex. Now suppose that a thread that is in a call to `printf()`, and so holds the lock on the mutex, is interrupted by a signal.

If the handler (being called by the thread that is still inside of `printf()`) itself calls `printf()`, the thread that holds the lock on the mutex will attempt to take it again, resulting in an instant deadlock.

To avoid interference between the handler and the operation, either ensure that the situation never arises (perhaps by masking off signals at critical moments) or invoke only Async-Signal-Safe operations from inside signal handlers.

Because setting a thread's mask is an inexpensive user-level operation, you can inexpensively make functions or sections of code fit in the Async-Signal-Safe category.

The only routines that POSIX guarantees to be Async-Signal-Safe are listed in Table 5–2. Any signal handler can safely call in to one of these functions.

TABLE 5–2   Async-Signal-Safe Functions

_exit()	fstat()	read()	sysconf()

Interrupted Waits on Condition Variables (Solaris Threads Only)

When a signal is delivered to a thread while the thread is waiting on a condition variable, the old convention (assuming that the process is not terminated) is that interrupted calls return EINTR.

The ideal new condition would be that when cond_wait(3T) and cond_timedwait(3T) return, the lock has been retaken on the mutex.

This is what is done in Solaris threads: when a thread is blocked in cond_wait() or cond_timedwait() and an unmasked, caught signal is delivered to the thread, the handler is invoked and the call to cond_wait() or cond_timedwait() returns EINTR with the mutex locked.

This implies that the mutex is locked in the signal handler because the handler might have to clean up after the thread. While this is true in the Solaris Operating Environment 2.5 release, it might change in the future, so do not rely on this behavior.

Note - In POSIX threads, `pthread_cond_wait(3T)` returns from signals, but this is not an error, `pthread_cond_wait()` returns zero as a spurious wake-up.

Handler cleanup is illustrated by Code Example 5–4.

CODE EXAMPLE 5–4   Condition Variables and Interrupted Waits

```
int sig_catcher() {
    sigset_t set;
    void hdlr();

    mutex_lock(&mut);

    sigemptyset(&set);
    sigaddset(&set, SIGINT);
    sigsetmask(SIG_UNBLOCK, &set, 0);

    if (cond_wait(&cond, &mut) == EINTR) {
        /* signal occurred and lock is held */
        cleanup();
        mutex_unlock(&mut);
        return(0);
    }
    normal_processing();
    mutex_unlock(&mut);
    return(1);
}

void hdlr() {
    /* lock is held in the handler */
    ...
}
```

Assume that the SIGINT signal is blocked in all threads on entry to `sig_catcher()` and that `hdlr()` has been established (with a call to `sigaction(2)`) as the handler for the SIGINT signal. When an unmasked and caught instance of the SIGINT signal is delivered to the thread while it is in `cond_wait()`, the thread first reacquires the lock on the mutex, then calls `hdlr()`, and then returns EINTR from `cond_wait()`.

Note that whether SA_RESTART has been specified as a flag to `sigaction()` has no effect here; `cond_wait(3T)` is not a system call and is not automatically restarted. When a caught signal occurs while a thread is blocked in `cond_wait()`, the call always returns EINTR. Again, the application should not rely on an interrupted `cond_wait()` reacquiring the mutex, because this behavior could change in the future.

I/O Issues

One of the attractions of multithreaded programming is I/O performance. The traditional UNIX API gave you little assistance in this area—you either used the facilities of the file system or bypassed the file system entirely.

This section shows how to use threads to get more flexibility through I/O concurrency and multibuffering. This section also discusses the differences and similarities between the approaches of synchronous I/O (with threads) and asynchronous I/O (with and without threads).

I/O as a Remote Procedure Call

In the traditional UNIX model, I/O appears to be synchronous, as if you were placing a remote procedure call to the I/O device. Once the call returns, then the I/O has completed (or at least it appears to have completed—a write request, for example, might merely result in the transfer of the data to a buffer in the operating environment).

The advantage of this model is that it is easy to understand because, as a programmer you are very familiar with the concept of procedure calls.

An alternative approach not found in traditional UNIX systems is the asynchronous model, in which an I/O request merely starts an operation. The program must somehow discover when the operation completes.

This approach is not as simple as the synchronous model, but it has the advantage of allowing concurrent I/O and processing in traditional, single-threaded UNIX processes.

Tamed Asynchrony

You can get most of the benefits of asynchronous I/O by using synchronous I/O in a multithreaded program. Where, with asynchronous I/O, you would issue a request and check later to determine when it completes, you can instead have a separate thread perform the I/O synchronously. The main thread can then check (perhaps by calling pthread_join(3T)) for the completion of the operation at some later time.

Asynchronous I/O

In most situations there is no need for asynchronous I/O, since its effects can be achieved with the use of threads, with each thread doing synchronous I/O. However, in a few situations, threads cannot achieve what asynchronous I/O can.

The most straightforward example is writing to a tape drive to make the tape drive stream. Streaming prevents the tape drive from stopping while it is being written to and moves the tape forward at high speed while supplying a constant stream of data that is written to tape.

To do this, the tape driver in the kernel must issue a queued write request when the tape driver responds to an interrupt that indicates that the previous tape-write operation has completed.

Threads cannot guarantee that asynchronous writes will be ordered because the order in which threads execute is indeterminate. Specifying the order of a write to a tape, for example, is not possible.

Asynchronous I/O Operations

```
#include <sys/asynch.h>

int aioread(int fildes, char *bufp, int bufs, off_t offset,

    int whence, aio_result_t *resultp);

int aiowrite(int filedes, const char *bufp, int bufs,
    off_t offset, int whence, aio_result_t *resultp);

aio_result_t *aiowait(const struct timeval *timeout);

int aiocancel(aio_result_t *resultp);
```

`aioread(3)` and `aiowrite(3)` are similar in form to `pread(2)` and `pwrite(2)`, except for the addition of the last argument. Calls to `aioread()` and `aiowrite()` result in the initiation (or queueing) of an I/O operation.

The call returns without blocking, and the status of the call is returned in the structure pointed to by *resultp*. This is an item of type `aio_result_t` that contains the following:

```
int aio_return;
int aio_errno;
```

When a call fails immediately, the failure code can be found in `aio_errno`. Otherwise, this field contains `AIO_INPROGRESS`, meaning that the operation has been successfully queued.

You can wait for an outstanding asynchronous I/O operation to complete by calling aiowait(3). This returns a pointer to the aio_result_t structure supplied with the original aioread(3) or aiowrite(3) call.

This time aio_result_t contains whatever read(2) or write(2) would have returned if one of them had been called instead of the asynchronous version. If the read() or write() is successful, aio_return contains the number of bytes that were read or written; if it was not successful, aio_return is -1, and aio_errno contains the error code.

aiowait() takes a *timeout* argument, which indicates how long the caller is willing to wait. As usual, a NULL pointer here means that the caller is willing to wait indefinitely, and a pointer to a structure containing a zero value means that the caller is unwilling to wait at all.

You might start an asynchronous I/O operation, do some work, then call aiowait() to wait for the request to complete. Or you can use SIGIO to be notified, asynchronously, when the operation completes.

Finally, a pending asynchronous I/O operation can be cancelled by calling aiocancel(). This routine is called with the address of the result area as an argument. This result area identifies which operation is being cancelled.

Shared I/O and New I/O System Calls

When multiple threads are performing I/O operations at the same time with the same file descriptor, you might discover that the traditional UNIX I/O interface is not thread safe. The problem occurs with nonsequential I/O. This uses the lseek(2) system call to set the file offset, which is then used in the next read(2) or write(2) call to indicate where in the file the operation should start. When two or more threads are issuing lseeks() to the same file descriptor, a conflict results.

To avoid this conflict, use the pread(2) and pwrite(2) system calls.

```
#include <sys/types.h>
#include <unistd.h>

ssize_t pread(int fildes, void *buf, size_t nbyte, off_t offset);

ssize_t pwrite(int filedes, void *buf, size_t nbyte,
    off_t offset);
```

These behave just like read(2) and write(2) except that they take an additional argument, the file offset. With this argument, you specify the offset without using lseek(2), so multiple threads can use these routines safely for I/O on the same file descriptor.

Alternatives to getc(3S) and putc(3S)

An additional problem occurs with standard I/O. Programmers are accustomed to routines such as getc(3S) and putc(3S) being very quick—they are implemented as macros. Because of this, they can be used within the inner loop of a program with no concerns about efficiency.

However, when they are made thread safe they suddenly become more expensive—they now require (at least) two internal subroutine calls, to lock and unlock a mutex.

To get around this problem, alternative versions of these routines are supplied, getc_unlocked(3S) and putc_unlocked(3S).

These do not acquire locks on a mutex and so are as quick as the original, nonthread-safe versions of getc(3S) and putc(3S).

However, to use them in a thread-safe way, you must explicitly lock and release the mutexes that protect the standard I/O streams, using flockfile(3S) and funlockfile(3S). The calls to these latter routines are placed outside the loop, and the calls to getc_unlocked() or putc_unlocked() are placed inside the loop.

Safe and Unsafe Interfaces

This chapter defines MT-safety levels for functions and libraries.

Thread Safety

Thread safety is the avoidance of data races—situations in which data are set to either correct or incorrect values, depending upon the order in which multiple threads access and modify the data.

When no sharing is intended, give each thread a private copy of the data. When sharing is important, provide explicit synchronization to make certain that the program behaves in a deterministic manner.

A procedure is thread safe when it is logically correct when executed simultaneously by several threads. At a practical level, it is convenient to recognize three levels of safety.

- Unsafe
- Thread safe - Serializable
- Thread safe - MT-Safe

An unsafe procedure can be made thread safe and serializable by surrounding it with statements to lock and unlock a mutex. Code Example 6–1 shows three simplified implementations of `fputs()`, initially thread unsafe.

Next is a serializable version of this routine with a single mutex protecting the procedure from concurrent execution problems. Actually, this is stronger synchronization than is usually necessary. When two threads are sending output to different files using fputs( ), one need not wait for the other—the threads need synchronization only when they are sharing an output file.

The last version is MT-safe. It uses one lock for each file, allowing two threads to print to different files at the same time. So, a routine is MT-safe when it is thread safe and its execution does not negatively affect performance.

CODE EXAMPLE 6–1   Degrees of Thread Safety

```
/* not thread-safe */
fputs(const char *s, FILE *stream) {
    char *p;
    for (p=s; *p; p++)
        putc((int)*p, stream);
}

/* serializable */
fputs(const char *s, FILE *stream) {
    static mutex_t mut;
    char *p;
    mutex_lock(&m);
    for (p=s; *p; p++)
        putc((int)*p, stream);

    mutex_unlock(&m);
}

/* MT-Safe */
mutex_t m[NFILE];
fputs(const char *s, FILE *stream) {
    static mutex_t mut;
    char *p;
    mutex_lock(&m[fileno(stream)]);
    for (p=s; *p; p++)
        putc((int)*p, stream);
    mutex_unlock(&m[fileno(stream)]0;
}
```

MT Interface Safety Levels

The threads man pages, man(3t) , use the safety level categories listed in Table 6–1 to describe how well an interface supports threads (these categories are explained more fully in the Intro(3) reference manual page).

TABLE 6–1 Interface Safety Levels

Category	Description
Safe	This code can be called from a multithreaded application
Safe with exceptions	See the NOTES sections of these pages for a description of the exceptions.
Unsafe	This interface is not safe to use with multithreaded applications unless the application arranges for only one thread at a time to execute within the library.
MT-Safe	This interface is fully prepared for multithreaded access in that it is both *safe* and it supports some concurrency.
MT-Safe with exceptions	See the NOTES sections of these pages in the man(3t): Library Routines for a list of the exceptions.
Async-Signal-Safe	This routine can safely be called from a signal handler. A thread that is executing an Async-Signal-Safe routine does not deadlock with itself when it is interrupted by a signal.
Fork1–Safe	This interface releases locks it has held whenever the Solaris fork1(2) or the POSIX fork(2) is called.

See the table in Appendix C, MT Safety Levels: Library Interfaces, for the safety levels of interfaces from the man(3): Library Routines. Check the man page to be sure of the level.

Some functions have purposely not been made safe for the following reasons.

- Making the interface MT-Safe would have negatively affected the performance of single-threaded applications.

- The library has an Unsafe interface. For example, a function might return a pointer to a buffer in the stack. You can use reentrant counterparts for some of these functions. The reentrant function name is the original function name with "_r" appended.

!	**Caution -** There is no way to be certain that a function with a name not ending in "_r" is MT-Safe other than by checking its reference manual page. Use of a function identified as not MT-Safe must be protected by a synchronizing device or by restriction to the initial thread.

Reentrant Functions for Unsafe Interfaces

For most functions with Unsafe interfaces, an MT-Safe version of the routine exists. The name of the new MT-Safe routine is always the name of the old Unsafe routine with "_r" appended. The Table 6–2 "_r" routines are supplied in the Solaris environment.

TABLE 6–2   Reentrant Functions

Async-Signal-Safe Functions

Functions that can safely be called from signal handlers are *Async-Signal-Safe*. The POSIX standard defines and lists Async-Signal-Safe functions (IEEE Std 1003.1-1990, 3.3.1.3 (3)(f), page 55). In addition to the POSIX Async-Signal-Safe functions, these three functions from the Solaris threads library are also Async- Signal-Safe.

- sema_post(3T)

- thr_sigsetmask(3T), similar to pthread_sigmask(3T)

- thr_kill(3T), similar to pthread_kill(3T)

MT Safety Levels for Libraries

All routines that can potentially be called by a thread from a multithreaded program should be MT-Safe.

This means that two or more activations of a routine must be able to *correctly* execute concurrently. So, every library interface that a multithreaded program uses must be MT-Safe.

Not all libraries are now MT-Safe. The commonly used libraries that are MT-Safe are listed in Table 6–3. Additional libraries will eventually be modified to be MT-Safe.

TABLE 6–3   Some MT-Safe Libraries

Library	Comments
lib/libc	Interfaces that are not safe have thread-safe interfaces of the form *_r (often with different semantics)
lib/libdl_stubs	To support static switch compiling

TABLE 6–3 Some MT-Safe Libraries *(continued)*

Library	Comments
lib/libintl	Internationalization library
lib/libm	Math library compliant with System V Interface Definition, Edition 3, X/Open and ANSI C
lib/libmalloc	Space-efficient memory allocation library; see malloc(3X)
lib/libmapmalloc	Alternative mmap(2)-based memory allocation library; see mapmalloc(3X)
lib/libnsl	The TLI interface, XDR, RPC clients and servers, netdir, netselect and getXXbyYY interfaces are not safe, but have thread-safe interfaces of the form getXXbyYY_r
lib/libresolv	Thread-specific errno support
lib/libsocket	Socket library for making network connections
lib/libw	Wide character and wide string functions for supporting multibyte locales
lib/straddr	Network name-to-address translation library
lib/libX11	X11 Windows library routines
lib/libC	C++ runtime shared objects

Unsafe Libraries

Routines in libraries that are not guaranteed to be MT-Safe can safely be called by multithreaded programs only when such calls are single threaded.

Compiling and Debugging

This chapter describes how to compile and debug multithreaded programs.

- "Compiling a Multithreaded Application" on page 175
- "Debugging a Multithreaded Program" on page 181

Compiling a Multithreaded Application

Many options are available for header files, define flags, and linking.

Preparing for Compilation

The following items are required to compile and link a multithreaded program. Except for the C compiler, all should come with your Solaris operating environment.

- A standard C compiler
- Include files:

  - `<thread.h>` and `<pthread.h>`
  - `<errno.h>`, `<limits.h>`, `<signal.h>`, `<unistd.h>`

- The regular Solaris linker, ln(1)
- The Solaris threads library (`libthread`), the POSIX threads library (`libpthread`), and possibly the POSIX realtime library (`libposix4`) for semaphores
- MT-safe libraries (`libc`, `libm`, `libw`, `libintl`, `libnsl`, `libsocket`, `libmalloc`, `libmapmalloc`, and so on)

175

Choosing Solaris or POSIX Semantics

Certain functions, including the ones listed in Table 7–1, have different semantics in the POSIX 1003.1c standard than in the Solaris 2.4 Operating Environment release, which was based on an earlier POSIX draft. Function definitions are chosen at compile time. See the man Pages(3): Library Routines for a description of the differences in expected parameters and return values.

TABLE 7–1   Functions With POSIX/Solaris Semantic Differences

`sigwait(2)`	
`ctime_r(3C)`	`asctime_r(3C)`
`ftrylockfile(3S)` - **new**	`getlogin_r(3C)`
`getgrnam_r(3C)`	`getgrgid_r(3C)`
`getpwnam_r(3C)`	`getpwuid_r(3C)`
`readdir_r(3C)`	`ttyname_r(3C)`

The Solaris fork(2) function duplicates all threads (*fork-all* behavior), while the POSIX fork(2) function duplicates only the calling thread (*fork-one* behavior), as does the Solaris `fork1()` function.

The handling of an alarm(2) is also different: a Solaris alarm goes to the thread's LWP, while a POSIX alarm goes to the whole process (see "Per-Thread Alarms" on page 149).

Including `<thread.h>` or `<pthread.h>`

The include file `<thread.h>`, used with the `-lthread` library, compiles code that is upward compatible with earlier releases of the Solaris Operating Environment. This library contains both interfaces—those with Solaris semantics and those with POSIX semantics. To call `thr_setconcurrency(3T)` with POSIX threads, your program needs to include `<thread.h>`.

The include file `<pthread.h>`, used with the `-lpthread` library, compiles code that is conformant with the multithreading interfaces defined by the POSIX 1003.1c standard. For complete POSIX compliance, the define flag `_POSIX_C_SOURCE` should be set to a (`long`) value ≥ `199506`:

```
cc [flags] file... -D_POSIX_C_SOURCE=N  (where N  199506L)
```

You can mix Solaris threads and POSIX threads in the same application, by including both <thread.h> and <pthread.h>, and linking with either the -lthread or -lpthread library.

In mixed use, Solaris semantics prevail when compiling with –D_REENTRANT and linking with -lthread, whereas POSIX semantics prevail when compiling with –D_POSIX_C_SOURCE and linking with -lpthread.

Defining _REENTRANT or _POSIX_C_SOURCE

For POSIX behavior, compile applications with the –D_POSIX_C_SOURCE flag set ≥ 199506L. For Solaris behavior, compile multithreaded programs with the –D_REENTRANT flag. This applies to every module of an application.

For mixed applications (for example, Solaris threads with POSIX semantics), compile with the –D_REENTRANT and –D_POSIX_PTHREAD_SEMANTICS flags.

To compile a single-threaded application, define neither the –D_REENTRANT nor the –D_POSIX_C_SOURCE flag. When these flags are not present, all the old definitions for errno, stdio, and so on, remain in effect.

Note - Compile single-threaded applications, not linked with either of the thread libraries (libthread.so.1 or libpthread.so.1), without the –D_REENTRANT flag. This eliminates performance degradation incurred when macros, such as putc(3s), are converted into reentrant function calls.

To summarize, POSIX applications that define -D_POSIX_C_SOURCE get the POSIX 1003.1c semantics for the routines listed in Table 7–1. Applications that define only –D_REENTRANT get the Solaris semantics for these routines. Solaris applications that define –D_POSIX_PTHREAD_SEMANTICS get the POSIX semantics for these routines, but can still use the Solaris threads interface.

Applications that define both -D_POSIX_C_SOURCE and –D_REENTRANT get the POSIX semantics.

Linking With libthread or libpthread

For POSIX threads behavior, load the libpthread library. For Solaris threads behavior, load the libthread library. Some POSIX programmers might want to link with –lthread to preserve the Solaris distinction between fork() and fork1(). All that -lpthread really does is to make fork() behave the same way as the Solaris fork1() call, and change the behavior of alarm(2).

To use libthread, specify −lthread before −lc on the ld command line, or last on the cc command line.

To use libpthread, specify −lpthread before −lc on the ld command line, or last on the cc command line.

Do not link a nonthreaded program with −lthread or −lpthread. Doing so establishes multithreading mechanisms at link time that are initiated at runtime. These slow down a single-threaded application, waste system resources, and produce misleading results when you debug your code.

Figure 7–1 summarizes the compile options.

Figure 7–1   Compilation Flowchart

In mixed usage, you need to include both thread.h and pthread.h.

All calls to libthread and libpthread are no-ops if the application does not link −lthread or −lpthread. The runtime library libc has many predefined libthread and libpthread stubs that are null procedures. True procedures are interposed by libthread or libpthread when the application links both libc and the thread library.

The behavior of the C library is undefined if a program is constructed with an ld command line that includes the following *incorrect* fragment:

```
 .o's ... -lc -lthread ... (this is incorrect)
 or
  .o's ... -lc -lpthread ... (this is incorrect)
```

Note - For C++ programs that use threads, use the –mt option, rather than
–lthread, to compile and link your application. The –mt option links with
libthread and ensures proper library linking order. Using –lthread might cause
your program to core dump.

Linking With -lposix4 for POSIX Semaphores

The Solaris semaphore routines, sema_*(3T), are contained in the libthread
library. By contrast, you link with the -lposix4 library to get the standard
sem_*(3R) POSIX 1003.1c semaphore routines described in "Semaphores" on page
122.

Link Old With New

Table 7–2 shows that multithreaded object modules should be linked with old object
modules only with great caution.

TABLE 7–2 Compiling With and Without the _REENTRANT Flag

The File Type	Compiled	Reference	And Return
Old object files (nonthreaded) and new object files	*Without* the _REENTRANT or _POSIX_C_SOURCE flag	Static storage	The traditional *errno*
New object files	*With* the _REENTRANT or _POSIX_C_SOURCE flag	__errno, the new binary entry point	The address of the thread's definition of errno
Programs using TLI in libnsl[1]	*With* the _REENTRANT or _POSIX_C_SOURCE flag (required)	__t_errno, a new entry point	The address of the thread's definition of t_errno.

1. Include tiuser.h to get the TLI global error variable.

Linking With the Alternate One-level libthread Library

The standard Solaris threads implementation is built upon a two-level threading model in which user-level threads are multiplexed over possibly fewer lightweight processes, or LWPs. An LWP is the fundamental unit of execution that is dispatched to a processor by the operating system. A mechanism is provided in the standard implementation for associating threads one-to-one with LWPs (the `THR_BOUND` and `PTHREAD_SCOPE_SYSTEM` flags) for writing applications with one-level semantics.

The Solaris 8 Operating Environment provides an alternate threads implementation of a one-level model in which user-level threads are associated one-to-one with LWPs. This implementation is simpler than the standard implementation and may be beneficial to some multithreaded applications. It provides exactly the same interfaces, both for POSIX threads and Solaris threads, as the standard implementation.

To link with the alternate implementation, use the following run-path –R option when linking the program.

For POSIX threads use:

```
cc -mt ... -lpthread ... -R /usr/lib/lwp        (32-bit)
cc -mt ... -lpthread ... -R /usr/lib/lwp/64     (64-bit)
```

For Solaris threads use:

```
cc -mt ... -R /usr/lib/lwp                      (32-bit)
cc -mt ... -R /usr/lib/lwp/64                   (64-bit)
```

For multithreaded programs that have been previously linked with the standard threads library, the environment variable `LD_LIBRARY_PATH` and `LD_LIBRARY_PATH_64` can be set as follows to bind the program at run time to the alternate threads library:

```
LD_LIBRARY_PATH=/usr/lib/lwp
LD_LIBRARY_PATH=/usr/lib/lwp:/usr/lib/lwp/64
```

Note that if an `LD_LIBRARY_PATH` environment variable is in effect for a secure process, then only the trusted directories specified by this variable will be used to augment the runtime linker's search rules.

When using the alternate one-level threads implementation, the library might create more LWPs than the standard implementation using unbound threads. LWPs consume operating system memory in contrast to threads, which consume only user-level memory. Thus, a multithreaded application linked with this library that creates thousands of threads would create an equal number of LWPs and might run the system out of resources required to support the application.

Debugging a Multithreaded Program

Common Oversights

The following list points out some of the more frequent oversights that can cause bugs in multithreaded programs.

- Passing a pointer to the caller's stack as an argument to a new thread.

- Accessing global memory (shared changeable state) without the protection of a synchronization mechanism.

- Creating deadlocks caused by two threads trying to acquire rights to the same pair of global resources in alternate order (so that one thread controls the first resource and the other controls the second resource and neither can proceed until the other gives up).

- Trying to reacquire a lock already held (recursive deadlock).

- Creating a hidden gap in synchronization protection. This is caused when a code segment protected by a synchronization mechanism contains a call to a function that frees and then reacquires the synchronization mechanism before it returns to the caller. The result is that it appears to the caller that the global data has been protected when it actually has not.

- Mixing UNIX signals with threads—it is better to use the `sigwait(2)` model for handling asynchronous signals.

- Using `setjmp(3B)` and `longjmp(3B)`, and then long-jumping away without releasing the mutex locks.

- Failing to reevaluate the conditions after returning from a call to `*_cond_wait(3T)` or `*_cond_timedwait(3T)`.

- Forgetting that default threads are created `PTHREAD_CREATE_JOINABLE` and must be reclaimed with `pthread_join(3T)`; note, `pthread_exit(3T)` does not free up its storage space.

- Making deeply nested, recursive calls and using large automatic arrays can cause problems because multithreaded programs have a more limited stack size than single-threaded programs.
- Specifying an inadequate stack size, or using non-default stacks.

And, note that multithreaded programs (especially those containing bugs) often behave differently in two successive runs, given identical inputs, because of differences in the thread scheduling order.

In general, multithreading bugs are statistical instead of deterministic. Tracing is usually a more effective method of finding order of execution problems than is breakpoint-based debugging.

Tracing and Debugging With the TNF Utilities

Use the TNF utilities (included as part of the Solaris system) to trace, debug, and gather performance analysis information from your applications and libraries. The TNF utilities integrate trace information from the kernel and from multiple user processes and threads, and so are especially useful for multithreaded code.

With the TNF utilities, you can easily trace and debug multithreaded programs. See the TNF utilities chapter in the *Programming Utilities Guide* for detailed information on using prex(1), tnfdump(1), and other TNF utilities.

Using truss(1)

See truss(1) for information on tracing system calls and signals.

Using adb(1)

When you bind all threads in a multithreaded program, a thread and an LWP are synonymous. Then you can access each thread with the following adb commands that support multithreaded programming.

TABLE 7–3 MT adb Commands

pid:A	Attaches to process # *pid*. This stops the process and all its LWPs.
:R	Detaches from process. This resumes the process and all its LWPs.
$L	Lists all active LWPs in the (stopped) process.

TABLE 7–3   MT `adb` Commands   *(continued)*

`n:l`	Switches focus to LWP # *n.*
`$l`	Shows the LWP currently focused.
`num:i`	Ignores signal number *num.*

These commands to set conditional breakpoints are often useful.

TABLE 7–4   Setting `adb` Breakpoints

`[`*label*`],[`*count*`]:b [`*expression*`]`	Breakpoint is detected when *expression* equals zero
foo`,ffff:b <g7-0xabcdef`	Stop at *foo* when *g7* = the hex value `0xABCDEF`

Using `dbx`

With the `dbx` utility you can debug and execute source programs written in C++, ANSI C, and FORTRAN. `dbx` accepts the same commands as the Debugger, but uses a standard terminal (TTY) interface. Both `dbx` and the Debugger support debugging multithreaded programs. For a full overview of `dbx` and Debugger features see the `dbx(1)` reference manual page and the *Using Sun Workshop* user's guide.

All the `dbx` options listed in Table 7–5 can support multithreaded applications.

TABLE 7–5   `dbx` Options for MT Programs

Option	Meaning
`cont at line [sig signo id]`	Continues execution at *line* with signal *signo.* The *id*, if present, specifies which thread or LWP to continue. The default value is *all.*
`lwp`	Displays current LWP. Switches to given LWP [lwpid].
`lwps`	Lists all LWPs in the current process.

TABLE 7–5 dbx Options for MT Programs *(continued)*

Option	Meaning
next ... tid	Steps the given thread. When a function call is skipped, all LWPs are implicitly resumed for the duration of that function call. Nonactive threads cannot be stepped.
next ... lid	Steps the given LWP. Does not implicitly resume all LWPs when skipping a function. The LWP on which the given thread is active. Does not implicitly resume all LWP when skipping a function.
step... tid	Steps the given thread. When a function call is skipped, all LWPs are implicitly resumed for the duration of that function call. Nonactive threads cannot be stepped.
step... lid	Steps the given LWP. Does not implicitly resume all LWPs when skipping a function.
stepi... lid	The given LWP.
stepi... tid	The LWP on which the given thread is active.
thread	Displays current thread. Switches to thread *tid.* In all the following variations, an optional tid implies the current thread.
thread -info [tid]	Prints everything known about the given thread.
thread -locks [tid]	Prints all locks held by the given thread.
thread -suspend [tid]	Puts the given thread into suspended state.
thread -continue [tid]	Unsuspends the given thread.
thread -hide [tid]	*Hides* the given (or current) thread. It will not appear in the generic threads listing.
thread -unhide [tid]	*Unhides* the given (or current) thread.
allthread-unhide	*Unhides* all threads.
threads	Prints the list of all known threads.

TABLE 7–5   dbx Options for MT Programs   *(continued)*

Option	Meaning
threads-all	Prints threads that are not usually printed (zombies).
all|filterthreads-mode	Controls whether threads prints all threads or filters them by default.
auto|manualthreads-mode	Enables automatic updating of the thread listing.
threads-mode	Echoes the current modes. Any of the previous forms can be followed by a thread or LWP ID to get the traceback for the specified entity.

Tools for Enhancing MT Programs

Sun provides several tools for enhancing the performance of MT programs. This chapter describes two of them.

LockLint verifies the consistent use of mutex and readers/writer locks in multithreaded ANSI C programs.

LockLint performs a static analysis of the use of mutex and readers/writer locks, and looks for inconsistent use of these locking techniques. In looking for inconsistent use of locks, LockLint detects the most common causes of data races and deadlocks.

LoopTool

LoopTool, along with its companion program LoopReport, profiles loops for FORTRAN programs; it provides information about programs parallelized by SPARCompiler FORTRAN MP. LoopTool displays a graph of loop runtimes, shows which loops were parallelized, and provides compiler hints as to why a loop was not parallelized.

LoopReport creates a summary table of all loop runtimes correlated with compiler hints about why a loop was not parallelized.

This chapter presents scenarios showing how each tool is used:

■ Scenario One ("Scenario: Checking a Program With LockLint" on page 188) shows the use of LockLint to check a Mandelbrot program's use of locks.

■ Scenario Two ("Scenario: Parallelizing Loops With LoopTool" on page 191) shows the use of LoopTool to parallelize portions of a library.

Scenario: Checking a Program With LockLint

A program can run efficiently but still contain potential problems. One such problem occurs when two threads try to access the same data simultaneously. This can lead to:

- Deadlocks — When two threads are mutually waiting for the other to release a lock.

- Data races — When two or more threads have overlapping read/write access to data, causing unexpected data values. For example, suppose Thread A writes the variable *calc*, goes off and does something else, and then comes back to read *calc*; in the meantime Thread B writes to *calc* and changes its value to something Thread A does not "expect."

Figure 8–1 shows how to use LockLint to see if data is adequately protected.

Figure 8–1   The LockLint Usage Flowchart

1. **Compile the program with LockLint instrumentation.**

   The compiler has an option to produce a version of the program that LockLint can use for analysis.

2. **Create a LockLint shell and load the instrumented program.**

   You can use this shell as you would any other, including running scripts.

3. **Save the executable's state.**

   LockLint is designed to run iteratively. You run it over and over, making progressively stronger assertions about the data it is analyzing, until you find a problem or are satisfied that the data is safe.

> **Note -** Analyzing the program with LockLint changes its state; that is, once you've done an analysis, you can't add further assertions. By saving and restoring the state, you can run the analysis over and over, with different assertions about the program's data.

4. **Analyze the program.**

   The `analyze` command performs consistency checks on the program's data.

5. **Search for unsafe data.**

   Having run the analysis, you can look for unprotected elements (see Code Example 8–1).

   The `held=[]` indicates that variables did not have locks consistently held on them while they were accessed. An asterisk preceding the `held=[]` indicates that these variables were written to. An asterisk, therefore, means that LockLint "believes" the data is not safe.

CODE EXAMPLE 8–1 Fragment of Initial LockLint Output

```
$ lock_lint analyze
   $ lock_lint vars -h | grep held
   :arrow_cursor        *held={ }
   :bottom_row         *held={ }
   :box_height         *held={ }
   :box_width          *held={ }
   :box_x          *held={ }
   :busy_cursor    *held={ }
   :c_text *held={ }
   :calc_mandel     *held={ }
   :calc_type   *held={ }
   :canvas *held={ }
   :canvas_proc/drag    *held={ }
   :canvas_proc/x   *held={ }
   [. . . ]
   :gap         *held={ }
   :gc         *held={ }
   :next_row          *held={ }
   :now.tv_sec         held={ }
   :now.tv_usec         held={ }
   :p_text          *held={ }
   :panel          *held={ }
   :picture_cols         *held={ }
   :picture_id          *held={ }
   :picture_rows         *held={ }
   :picture_state         *held={ }
   :pw          *held={ }
   :ramp.blue         *held={ }
   :ramp.green          *held={ }
   :ramp.red          *held={ }
   :rectangle_selected *held={ }
   :row_inc         *held={ }
   :run_button          *held={ }
```

```
[ . . . ]
```

However, this analysis is limited in its usefulness because many of the variables displayed do not *need* to be protected (such as variables that are not written to, except when they're initialized). By excluding some data from consideration, and having LockLint repeat its analyses, you can narrow your search to the unprotected variables that you are interested in.

6. **Restore the program to its saved state.**

   To be able to run the analysis again, pop the state back to what it was before the program was last analyzed.

7. **Refine the analysis by excluding some data.**

   For example, you can ignore variables that aren't written to—since they don't change, they won't cause data races. And you can ignore places where the variables are initialized (if they're not visible to other threads).

   You can ignore the variables that you know are safe by making *assertions* about them. In the code example below, the following is done:

   - Initialization functions are ignored because no data is overwritten at initialization.
   - Some variables are asserted to be read-only.

   For illustration, this is done on the command line in verbose mode. After you become familiar with the command syntax, you can use aliases and shell scripts to make the task easier.

```
$ lock_lint ignore CreateXStuff run_proc canvas_proc main
  $ lock_lint assert read only bottom_row
  $ lock_lint assert read only calc_mandel
  etc.
```

8. **Analyze the program again, and search for unsafe data.**

   The list of unsafe data is considerably reduced, as shown in Code Example 8–2.

   CODE EXAMPLE 8–2   Unsafe Data Reported by LockLint

```
$ lock_lint vars -h | grep held
  :bottom_row        held={ }
  :calc_mandel        held={ }
  :colors        held={ }
  :corner_i        held={ }
  :corner_r        held={ }
  :display        held={ }
  :drawable        held={ }
  :frame        held={ }
  :gap        held={ }
  :gc        held={ }
  :next_row        held={
  mandel_display.c:next_row_lock }
```

```
:picture_cols          held={ }
:picture_id          held={ }
:picture_rows          *held={ }
:picture_state           *held={ }
:row_inc          held={ }
```

Only two variables were written to (*picture_rows* and *picture_state*) and are flagged by `LockLint` as inconsistently protected.

The analysis also flags the variable *next_row*, which the calculator threads use to find the next chunk of work to be done. However, as the analysis states, this variable is consistently protected.

Alter your source code to properly protect *picture_rows* and *picture_state*.

Scenario: Parallelizing Loops With LoopTool

IMSL is a popular math library used by many FORTRAN and C programmers.[1] One of its routines is a good candidate for parallelizing with LoopTool.

This example is a FORTRAN program called `l2trg.f( )`. (It computes LU factorization of a single-precision general matrix.) The program is compiled without any parallelization, then checked to see how long it takes to run with the time(1) command.

CODE EXAMPLE 8–3   Original Times for `l2trg.f( )` (Not Parallelized)

```
$ f77 l2trg.f -cg92 -03 -lmsl
$ /bin/time a.out
real   44.8
user   43.5
sys   1.0
```

To look at the program with LoopTool, recompile with the LoopTool instrumentation, using the −Zlp option.

```
$ f77 l2trg.f -cg92 -03 -Zlp -lmsl
```

Start LoopTool. Figure 8–2 shows the initial Overview screen.

---

1. IMSL is a registered trademark of IMSL, Inc. This example is used with permission.
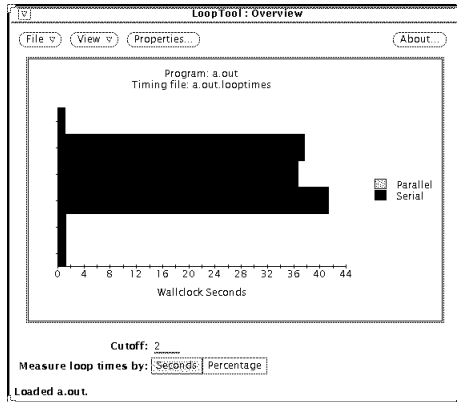

Figure 8–2   LoopTool View Before Parallelization

Most of the program's time is spent in three loops; each loop indicated by a horizontal bar.

The LoopTool user interface displays various screens triggered by cursor movement and mouse actions. In the Overview window:

Put the cursor over a loop to get its line number.

Click the loop to open a window that displays the loop's source code.

In the example, a click on the middle horizontal bar displays the source code for the middle loop. The source code reveals that loops are nested.

Figure 8–3 shows the Source and Hints window for the middle loop.
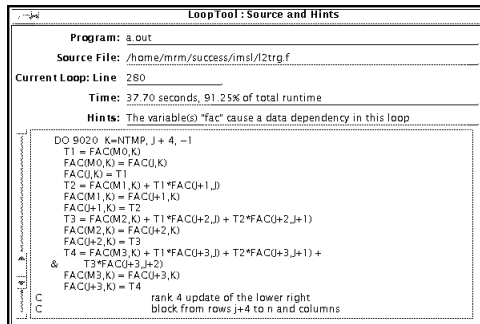

Figure 8–3   LoopTool (Source and Hints Window)

In this case, LoopTool gives the Hints message:

```
The variable ``fac'' causes a data dependency in this loop
```

In the source code, you can see that *fac* is calculated in the nested, innermost loop (9030):

```
C                       update the remaining rectangular
C                       block of U, rows j to j+3 and
```

```
C                     columns j+4 to n

      DO 9020  K=NTMP, J + 4, -1
         T1 = FAC(M0,K)
         FAC(M0,K) = FAC(J,K)
         FAC(J,K) = T1
         T2 = FAC(M1,K) + T1*FAC(J+1,J)
         FAC(M1,K) = FAC(J+1,K)
         FAC(J+1,K) = T2
         T3 = FAC(M2,K) + T1*FAC(J+2,J) + T2*FAC(J+2,J+1)
         FAC(M2,K) = FAC(J+2,K)
         FAC(J+2,K) = T3
         T4 = FAC(M3,K) + T1*FAC(J+3,J) + T2*FAC(J+3,J+1) +
     &        T3*FAC(J+3,J+2)
         FAC(M3,K) = FAC(J+3,K)
         FAC(J+3,K) = T4
C                     rank 4 update of the lower right
C                     block from rows j+4 to n and columns
C                     j+4 to n
         DO 9030  I=KBEG, NTMP
            FAC(I,K) = FAC(I,K) + T1*FAC(I,J) + T2*FAC(I,J+1) +
     &                 T3*FAC(I,J+2) + T4*FAC(I,J+3)
 9030    CONTINUE
 9020 CONTINUE
```

The loop index, *I*, of the innermost loop is used to access rows of the array *fac*. So the innermost loop updates the *I*th row of *fac*. Since updating these rows does not depend on updates of any other rows of *fac*, it's safe to parallelize this loop.

The calculation of *fac* is speeded up by parallelizing loop 9030, so there should be a significant performance improvement. Force explicit parallelization by inserting a DOALL directive in front of loop 9030:

```
C$PAR DOALL
(Add DOALL directive here)
       DO 9030  I=KBEG, NTMP
          FAC(I,K) = FAC(I,K) + T1*FAC(I,J) + T2*FAC(I,J+1) +
     &               T3*FAC(I,J+2) + T4*FAC(I,J+3)
 9030     CONTINUE
```

Now you can recompile the FORTRAN code, run the program, and compare the new time with the original times. More specifically, Code Example 8–3 shows the use of all the processors on the machine by setting the PARALLEL environment variable equal to 2, and forces explicit parallelization of that loop with the −explicitpar compiler option.

Finally, run the program and compare its time with that of the original times (shown in Code Example 8–4).

CODE EXAMPLE 8–4   Post-Parallelization Times for l2trg.f( )

```
$ setenv PARALLEL 2
(2 is the # of processors on the machine)
$ f77 l2trg.f -cg92 -03 -explicitpar -imsl
$ /bin/time a.out
```

```
real   28.4
user   53.8
sys    1.1
```

The program now runs over a third faster. (The higher number for *user* reflects the fact that there are now two processes running.) Figure 8–4 shows the `LoopTool` Overview window. You see that, in fact, the innermost loop is now parallel.

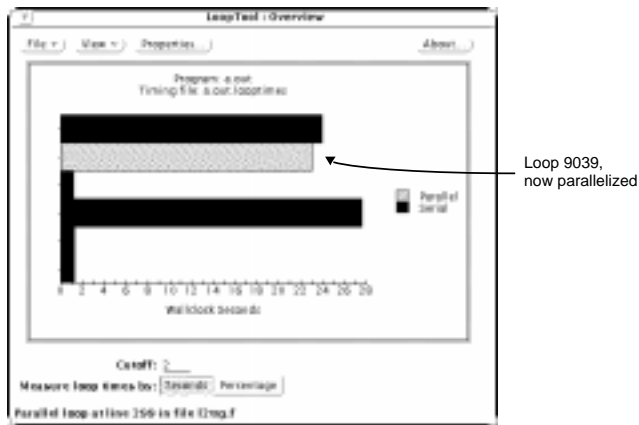

Figure 8–4   `LoopTool` View After Parallelization

For More Information

LoopTool User's Guide 801-6693-10

Programming With Solaris Threads

This chapter compares the Application Programming Interface (API) for Solaris and POSIX threads, and explains the Solaris features that are not found in POSIX threads.

Comparing APIs for Solaris Threads and POSIX Threads

The Solaris threads API and the pthreads API are two solutions to the same problem: building parallelism into application software. Although each API is complete in itself, you can safely mix Solaris threads functions and pthread functions in the same program.

The two APIs do not match exactly, however. Solaris threads supports functions that are not found in pthreads, and pthreads includes functions that are not supported in the Solaris interface. For those functions that *do* match, the associated arguments might not, although the information content is effectively the same.

By combining the two APIs, you can use features not found in one to enhance the other. Similarly, you can run applications using Solaris threads, exclusively, with applications using pthreads, exclusively, on the same system.

Major API Differences

Solaris threads and pthreads are very similar in both API action and syntax. The major differences are listed in Table 9–1.

TABLE 9–1 Unique Solaris Threads and pthreads Features

Solaris Threads (libthread)	POSIX Threads (libpthread)
`thr_` prefix for threads function names; `sema_` prefix for semaphore function names	`pthread_` prefix for pthreads function names; `sem_` prefix for semaphore function names
Readers/Writer locks	Attribute objects (these replace many Solaris arguments or flags with pointers to pthreads attribute objects)
Ability to create "daemon" threads	Cancellation semantics
Suspending and continuing a thread	Scheduling policies
Setting concurrency (requesting a new LWP): determining concurrency level	

Function Comparison Table

The following table compares Solaris threads functions with pthreads functions. Note that even when Solaris threads and pthreads functions appear to be essentially the same, the arguments to the functions can differ.

When a comparable interface is not available either in pthreads or Solaris threads, a hyphen '-' appears in the column. Entries in the pthreads column that are followed by "POSIX 1003.4" or "POSIX.4" are part of the POSIX Realtime standard specification and are not part of pthreads.

To use the Solaris threads functions described in this chapter, you must link with the Solaris threads library −lthread).

Where functionality is virtually the same for both Solaris threads and for pthreads, (even though the function names or arguments might differ), only a brief example

consisting of the correct include file and the function prototype is presented. Where return values are not given for the Solaris threads functions, see the appropriate pages in man(3): Library Routines for the function return values.

For more information on Solaris related functions, see the related pthreads documentation for the similarly named function.

Where Solaris threads functions offer capabilities that are not available in pthreads, a full description of the functions is provided.

Unique Solaris Threads Functions

- "Suspend Thread Execution" on page 202
- "Continue a Suspended Thread" on page 203
- "Set Thread Concurrency Level" on page 204
- "Get Thread Concurrency" on page 205

Suspend Thread Execution

thr_suspend(3T)

`thr_suspend(3T)` immediately suspends the execution of the thread specified by target_thread. On successful return from `thr_suspend()`, the suspended thread is no longer executing.

Once a thread is suspended, subsequent calls to `thr_suspend()` have no effect. Signals cannot awaken the suspended thread; they remain pending until the thread resumes execution.

```
#include <thread.h>

int thr_suspend(thread_t tid);
```

In the following synopsis, `pthread_t` *tid* as defined in pthreads is the same as `thread_t` *tid* in Solaris threads. *tid* values can be used interchangeably either by assignment or through the use of casts.

```
thread_t tid; /* tid from thr_create() */

/* pthreads equivalent of Solaris tid from thread created */
/* with pthread_create() */
pthread_t ptid;

int ret;
```

```
ret = thr_suspend(tid);

/* using pthreads ID variable with a cast */
ret = thr_suspend((thread_t) ptid);
```

Return Values

`thr_suspend()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, `thr_suspend()` fails and returns the corresponding value.

ESRCH

   tid cannot be found in the current process.

Continue a Suspended Thread

thr_continue(3T)

 `thr_continue`(3T) resumes the execution of a suspended thread. Once a suspended thread is continued, subsequent calls to `thr_continue()` have no effect.

```
#include <thread.h>

int thr_continue(thread_t tid);
```

A suspended thread will not be awakened by a signal. The signal stays pending until the execution of the thread is resumed by `thr_continue()`.

`pthread_t` *tid* as defined in pthreads is the same as `thread_t` *tid* in Solaris threads. *tid* values can be used interchangeably either by assignment or through the use of casts.

```
thread_t tid; /* tid from thr_create()*/

/* pthreads equivalent of Solaris tid from thread created */
/* with pthread_create()*/
pthread_t ptid;

int ret;

ret = thr_continue(tid);

/* using pthreads ID variable with a cast */
ret = thr_continue((thread_t) ptid)
```

`thr_continue()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When the following condition occurs, `thr_continue()` fails and returns the corresponding value.

ESRCH

   tid cannot be found in the current process.

Set Thread Concurrency Level

By default, Solaris threads attempt to adjust the system execution resources (LWPs) used to run unbound threads to match the real number of active threads. While the Solaris threads package cannot make perfect decisions, it at least ensures that the process continues to make progress.

When you have some idea of the number of unbound threads that should be simultaneously active (executing code or system calls), tell the library through `thr_setconcurrency()`. To get the number of threads being used, use `thr_getconcurrency()`.

thr_setconcurrency(3T)

 `thr_setconcurrency`(3T) provides a hint to the system about the required level of concurrency in the application. The system ensures that a sufficient number of threads are active so that the process continues to make progress.

```
#include <thread.h>

int new_level;
int ret;

ret = thr_setconcurrency(new_level);
```

Unbound threads in a process might or might not be required to be simultaneously active. To conserve system resources, the threads system ensures by default that enough threads are active for the process to make progress, and that the process will not deadlock through a lack of concurrency.

Because this might not produce the most effective level of concurrency, `thr_setconcurrency()` permits the application to give the threads system a hint, specified by *new_level*, for the desired level of concurrency.

The actual number of simultaneously active threads can be larger or smaller than *new_level*.

Note that an application with multiple compute-bound threads can fail to schedule all the runnable threads if `thr_setconcurrency()` has not been called to adjust the level of execution resources.

You can also affect the value for the desired concurrency level by setting the `THR_NEW_LWP` flag in `thr_create()`. This effectively increments the current level by one.

Return Values

Returns a zero when it completes successfully. Any other returned value indicates that an error occurred. When any of the following conditions is detected, `thr_setconcurrency()` fails and returns the corresponding value.

`EAGAIN`

   The specified concurrency level would cause a system resource to be exceeded.

`EINVAL`

   The value for *new_level* is negative.

Get Thread Concurrency

thr_getconcurrency(3T)

Use `thr_getconcurrency`(3T) to get the current value of the concurrency level previously set by `thr_setconcurrency()`. Note that the actual number of simultaneously active threads can be larger or smaller than this number.

```
#include <thread.h>
```

```
int thr_getconcurrency(void)
```

Return Value

`thr_getconcurrency()` always returns the current value for the desired concurrency level.

Similar Synchronization Functions—Read-Write Locks

Read-write locks allow simultaneous read access by many threads while restricting write access to only one thread at a time.

- "Initialize a Read-Write Lock" on page 206

- "Acquire a Read Lock" on page 208

- "Try to Acquire a Read Lock" on page 208

- "Acquire a Write Lock" on page 209

- "Try to Acquire a Write Lock" on page 210

- "Unlock a Read-Write Lock" on page 210

- "Destroy Read-Write Lock State" on page 211

When any thread holds the lock for reading, other threads can also acquire the lock for reading but must wait to acquire the lock for writing. If one thread holds the lock for writing, or is waiting to acquire the lock for writing, other threads must wait to acquire the lock for either reading or writing.

Read-write locks are slower than mutexes, but can improve performance when they protect data that are not frequently written but that are read by many concurrent threads.

Use read-write locks to synchronize threads in this process and other processes by allocating them in memory that is writable and shared among the cooperating processes (see mmap(2)) and by initializing them for this behavior.

By default, the acquisition order is not defined when multiple threads are waiting for a read-write lock. However, to avoid writer starvation, the Solaris threads package tends to favor writers over readers.

Read-write locks must be initialized before use.

Initialize a Read-Write Lock

rwlock_init(3T)

```
#include <synch.h>  (or #include <thread.h>)

int rwlock_init(rwlock_t *rwlp, int type, void * arg);
```

Use `rwlock_init`(3T) to initialize the read-write lock pointed to by *rwlp* and to set the lock state to unlocked. *type* can be one of the following (note that *arg* is currently ignored). (For POSIX threads, see "pthread_rwlock_init(3T)" on page 134.)

- `USYNC_PROCESS` The read-write lock can be used to synchronize threads in this process and other processes. *arg* is ignored.

- `USYNC_THREAD` The read-write lock can be used to synchronize threads in this process, only. *arg* is ignored.

Multiple threads must not initialize the same read-write lock simultaneously. Read-write locks can also be initialized by allocation in zeroed memory, in which case a type of `USYNC_THREAD` is assumed. A read-write lock must not be reinitialized while other threads might be using it.

Initializing Read-Write Locks With Intraprocess Scope

```
#include <thread.h>

rwlock_t rwlp;
int ret;

/* to be used within this process only */
ret = rwlock_init(&rwlp, USYNC_THREAD, 0);
```

Initializing Read-Write Locks With Interprocess Scope

```
#include <thread.h>

rwlock_t rwlp;
int ret;

/* to be used among all processes */
ret = rwlock_init(&rwlp, USYNC_PROCESS, 0);
```

Return Values

`rwlock_init()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

   Invalid argument.

EFAULT

   rwlp or *arg* points to an illegal address.

Acquire a Read Lock

rw_rdlock(3T)

```
#include <synch.h> (or #include <thread.h>)
```

```
int rw_rdlock(rwlock_t *rwlp);
```

Use `rw_rdlock`(3T) to acquire a read lock on the read-write lock pointed to by *rwlp*. When the read-write lock is already locked for writing, the calling thread blocks until the write lock is released. Otherwise, the read lock is acquired. (For POSIX threads, see "pthread_rwlock_rdlock(3T)" on page 135.)

Return Values

`rw_rdlock( )` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

```
EINVAL
```

   Invalid argument.

```
EFAULT
```

   rwlp points to an illegal address.

Try to Acquire a Read Lock

rw_tryrdlock(3T)

```
#include <synch.h>  (or #include <thread.h>)
```

```
int rw_tryrdlock(rwlock_t *rwlp);
```

Use `rw_tryrdlock`(3T) to attempt to acquire a read lock on the read-write lock pointed to by *rwlp*. When the read-write lock is already locked for writing, it returns an error. Otherwise, the read lock is acquired. (For POSIX threads, see "pthread_rwlock_tryrdlock(3T)" on page 136.)

Return Values

`rw_tryrdlock()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

`EINVAL`

Invalid argument.

`EFAULT`

rwlp points to an illegal address.

`EBUSY`

The read-write lock pointed to by *rwlp* was already locked.

Acquire a Write Lock

rw_wrlock(3T)

`#include <synch.h>` *(or* `#include <thread.h>`*)*

`int rw_wrlock(rwlock_t *rwlp);`

Use `rw_wrlock`(3T) to acquire a write lock on the read-write lock pointed to by *rwlp*. When the read-write lock is already locked for reading or writing, the calling thread blocks until all the read locks and write locks are released. Only one thread at a time can hold a write lock on a read-write lock. (For POSIX threads, see "pthread_rwlock_wrlock(3T)" on page 136.)

Return Values

`rw_wrlock()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

`EINVAL`

Invalid argument.

`EFAULT`

rwlp points to an illegal address.

Try to Acquire a Write Lock

rw_trywrlock(3T)

```
#include <synch.h>  (or #include <thread.h>)

int rw_trywrlock(rwlock_t *rwlp);
```

Use `rw_trywrlock`(3T) to attempt to acquire a write lock on the read-write lock pointed to by *rwlp*. When the read-write lock is already locked for reading or writing, it returns an error. (For POSIX threads, see "pthread_rwlock_trywrlock(3T)" on page 137.)

Return Values

`rw_trywrlock()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

`EINVAL`

Invalid argument.

`EFAULT`

rwlp points to an illegal address.

`EBUSY`

The read-write lock pointed to by *rwlp* was already locked.

Unlock a Read-Write Lock

rw_unlock(3T)

```
#include <synch.h>  (or #include <thread.h>)

int rw_unlock(rwlock_t *rwlp);
```

Use `rw_unlock`(3T) to unlock a read-write lock pointed to by *rwlp*. The read-write lock must be locked and the calling thread must hold the lock either for reading or writing. When any other threads are waiting for the read-write lock to become available, one of them is unblocked. (For POSIX threads, see "pthread_rwlock_unlock(3T)" on page 138.)

Return Values

`rw_unlock()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

   Invalid argument.

EFAULT

   rwlp points to an illegal address.

Destroy Read-Write Lock State

rwlock_destroy(3T)

`#include <synch.h>`   *(or* `#include <thread.h>`*)*

`int rwlock_destroy(rwlock_t *rwlp);`

Use `rwlock_destroy`(3T) to destroy any state associated with the read-write lock pointed to by *rlwp*. The space for storing the read-write lock is not freed. (For POSIX threads, see "pthread_rwlock_destroy(3T)" on page 139.)

Return Values

`rwlock_destroy()` returns zero after completing successfully. Any other returned value indicates that an error occurred. When any of the following conditions occurs, the function fails and returns the corresponding value.

EINVAL

   Invalid argument.

EFAULT

   rwlp points to an illegal address.

Read-Write Lock Example

Code Example 9–1 uses a bank account to demonstrate read-write locks. While the program could allow multiple threads to have concurrent read-only access to the account balance, only a single writer is allowed. Note that the get_balance() function

needs the lock to ensure that the addition of the checking and saving balances occurs atomically.

CODE EXAMPLE 9–1   Read-Write Bank Account

```
rwlock_t account_lock;
float checking_balance = 100.0;
float saving_balance = 100.0;
...
rwlock_init(&account_lock, 0, NULL);
...

float
get_balance() {
    float bal;

    rw_rdlock(&account_lock);
    bal = checking_balance + saving_balance;
    rw_unlock(&account_lock);
    return(bal);
}

void
transfer_checking_to_savings(float amount) {
    rw_wrlock(&account_lock);
    checking_balance = checking_balance - amount;
    saving_balance = saving_balance + amount;
    rw_unlock(&account_lock);
}
```

Create a Thread

The thr_create(3T) routine is one of the most elaborate of all the Solaris threads library routines.

thr_create(3T)

Use thr_create(3T) to add a new thread of control to the current process. (For POSIX threads, see "pthread_create(3T)" on page 30.)

Note that the new thread does not inherit pending signals, but it does inherit priority and signal masks.

```
#include <thread.h>

int thr_create(void *stack_base, size_t stack_size,
    void *(*start_routine) (void *), void *arg, long flags,
    thread_t *new_thread);

size_t thr_min_stack(void);
```

stack_base—Contains the address for the stack that the new thread uses. If *stack_base* is NULL then thr_create() allocates a stack for the new thread with at least *stack_size* bytes.

stack_size—Contains the size, in number of bytes, for the stack that the new thread uses. If *stack_size* is zero, a default size is used. In most cases, a zero value works best. If *stack_size* is not zero, it must be greater than the value returned by thr_min_stack().

There is no general need to allocate stack space for threads. The threads library allocates 1 Mbyte of virtual memory for each thread's stack with no swap space reserved. (The library uses the –MAP_NORESERVE option of mmap(2) to make the allocations.)

start_routine—Contains the function with which the new thread begins execution. When start_routine() returns, the thread exits with the exit status set to the value returned by *start_routine* (see "thr_exit(3T)" on page 218).

arg—Can be anything that is described by void, which is typically any 4-byte value. Anything larger must be passed indirectly by having the argument point to it.

Note that you can supply only one argument. To get your procedure to take multiple arguments, encode them as one (such as by putting them in a structure).

flags---( )Specifies attributes for the created thread. In most cases a zero value works best.

The value in *flags* is constructed from the bitwise inclusive OR of the following:

- THR_SUSPENDED—Suspends the new thread and does not execute *start_routine* until the thread is started by thr_continue(). Use this to operate on the thread (such as changing its priority) before you run it. The termination of a detached thread is ignored.

- THR_DETACHED—Detaches the new thread so that its thread ID and other resources can be reused as soon as the thread terminates. Set this when you do not want to wait for the thread to terminate.

Note - When there is no explicit synchronization to prevent it, an unsuspended, detached thread can die and have its thread ID reassigned to another new thread before its creator returns from thr_create().

- THR_BOUND—Permanently binds the new thread to an LWP (the new thread is a *bound thread*).

- THR_NEW_LWP—Increases the concurrency level for unbound threads by one. The effect is similar to incrementing concurrency by one with thr_setconcurrency(3T), although THR_NEW_LWP does not affect the level set through the thr_setconcurrency() function. Typically, THR_NEW_LWP adds a new LWP to the pool of LWPs running unbound threads.

- When you specify both THR_BOUND and THR_NEW_LWP, two LWPs are typically created—one for the bound thread and another for the pool of LWPs running unbound threads.

- THR_DAEMON—Marks the new thread as a daemon. The process exits when all nondaemon threads exit. Daemon threads do not affect the process exit status and are ignored when counting the number of thread exits.

  A process can exit either by calling exit() or by having every thread in the process that was not created with the THR_DAEMON flag call thr_exit(3T). An application, or a library it calls, can create one or more threads that should be ignored (not counted) in the decision of whether to exit. The THR_DAEMON flag identifies threads that are not counted in the process exit criterion.

new_thread—Points to a location (when *new_thread* is not NULL) where the ID of the new thread is stored when thr_create() is successful. The caller is responsible for supplying the storage this argument points to. The ID is valid only within the calling process.

If you are not interested in this identifier, supply a zero value to *new_thread*.

Return Values

Returns a zero and exits when it completes successfully. Any other returned value indicates that an error occurred. When any of the following conditions is detected, thr_create() fails and returns the corresponding value.

EAGAIN

  A system limit is exceeded, such as when too many LWPs have been created.

ENOMEM

  Not enough memory was available to create the new thread.

EINVAL

  stack_base is not NULL and *stack_size* is less than the value returned by thr_min_stack.()

Stack Behavior

Stack behavior in Solaris threads is generally the same as that in pthreads. For more information about stack setup and operation, see "About Stacks" on page 71.

You can get the absolute minimum on stack size by calling thr_min_stack(), which returns the amount of stack space required for a thread that executes a null procedure. Useful threads need more than this, so be very careful when reducing the stack size.

You can specify a custom stack in two ways. The first is to supply a NULL for the stack location, thereby asking the runtime library to allocate the space for the stack, but to supply the desired size in the stacksize parameter to thr_create().

The other approach is to take overall aspects of stack management and supply a pointer to the stack to thr_create(). This means that you are responsible not only for stack allocation but also for stack deallocation—when the thread terminates, you must arrange for the disposal of its stack.

When you allocate your own stack, be sure to append a red zone to its end by calling mprotect(2).

Get the Minimal Stack Size

thr_min_stack(3T)

Use thr_min_stack(3T) to get the minimum stack size for a thread.

```
#include <thread.h>
```

```
size_t thr_min_stack(void);
```

thr_min_stack() returns the amount of space needed to execute a null thread (a null thread is a thread that is created to execute a null procedure).

A thread that does more than execute a null procedure should allocate a stack size greater than the size of thr_min_stack().

When a thread is created with a user-supplied stack, the user must reserve enough space to run the thread. In a dynamically linked execution environment, it is difficult to know what the thread minimal stack requirements are.

Most users should not create threads with user-supplied stacks. User-supplied stacks exist only to support applications that require complete control over their execution environments.

Instead, users should let the threads library manage stack allocation. The threads library provides default stacks that should meet the requirements of any created thread.

Get the Thread Identifier

thr_self(3T)

Use `thr_self`(3T) to get the ID of the calling thread. (For POSIX threads, see "pthread_self(3T)" on page 40.)

```
#include <thread.h>

thread_t thr_self(void);
```

Yield Thread Execution

thr_yield(3T)

 `thr_yield`(3T) causes the current thread to yield its execution in favor of another thread with the same or greater priority; otherwise it has no effect. There is no guarantee that a thread calling `thr_yield()` will do so.

```
#include <thread.h>

void thr_yield(void);
```

Send a Signal to a Thread

thr_kill(3T)

 `thr_kill`(3T) sends a signal to a thread. (For POSIX threads, see "pthread_kill(3T)" on page 44.)

```
#include <thread.h>
#include <signal.h>

int thr_kill(thread_t target_thread, int sig);
```

Access the Signal Mask of the Calling Thread

thr_sigsetmask(3T)

Use `thr_sigsetmask`(3T) to change or examine the signal mask of the calling thread.

```
#include <thread.h>
#include <signal.h>
```

```
int thr_sigsetmask(int how, const sigset_t *set, sigset_t *oset);
```

Terminate a Thread

thr_exit(3T)

Use `thr_exit`(3T) to terminate a thread. (For POSIX threads, see
"pthread_exit(3T)" on page 46.)

```
#include <thread.h>

void thr_exit(void *status);
```

Wait for Thread Termination

thr_join(3T)

Use `thr_join`(3T) to wait for a thread to terminate. (For POSIX threads, see
"pthread_join(3T)" on page 31.)

```
#include <thread.h>

int thr_join(thread_t tid, thread_t *departedid, void **status);
```

Join specific

```
#include <thread.h>

thread_t tid;
thread_t departedid;
int ret;
int status;

/* waiting to join thread "tid" with status */
ret = thr_join(tid, &departedid, (void**)&status);

/* waiting to join thread "tid" without status */
ret = thr_join(tid, &departedid, NULL);

/* waiting to join thread "tid" without return id and status */
ret = thr_join(tid, NULL, NULL);
```

When the *tid* is (thread_t)0, then thread_join() waits for any undetached
thread in the process to terminate. In other words, when no thread identifier is
specified, any undetached thread that exits causes thread_join() to return.

Join any

```
#include <thread.h>

thread_t tid;
thread_t departedid;
int ret;
int status;

/* waiting to join thread "tid" with status */
ret = thr_join(NULL, &departedid, (void **)&status);
```

By indicating NULL as thread id in the Solaris thr_join(), a join will take place when any non detached thread in the process exits. The *departedid* will indicate the thread ID of exiting thread.

Create a Thread-Specific Data Key

Except for the function names and arguments, thread specific data is the same for Solaris as it is for POSIX. The synopses for the Solaris functions are given in this section.

thr_keycreate(3T)

thr_keycreate(3T) allocates a key that is used to identify thread-specific data in a process. (For POSIX threads, see "pthread_key_create(3T)" on page 35.)

```
#include <thread.h>

int thr_keycreate(thread_key_t *keyp,
    void (*destructor) (void *value));
```

Set the Thread-Specific Data Key

thr_setspecific(3T)

thr_setspecific(3T) binds *value* to the thread-specific data key, *key*, for the calling thread. (For POSIX threads, see "pthread_setspecific(3T)" on page 37.)

```
#include <thread.h>

int thr_setspecific(thread_key_t key, void *value);
```

Get the Thread-Specific Data Key

thr_getspecific(3T)

`thr_getspecific`(3T) stores the current value bound to *key* for the calling thread into the location pointed to by *valuep*. (For POSIX threads, see "pthread_getspecific(3T)" on page 37.)

```
#include <thread.h>

int thr_getspecific(thread_key_t key, void **valuep);
```

Set the Thread Priority

In Solaris threads, if a thread is to be created with a priority other than that of its parent's, it is created in SUSPEND mode. While suspended, the threads priority is modified using the `thr_setprio(3T)` function call; then it is continued.

An unbound thread is usually scheduled only with respect to other threads in the process using simple priority levels with no adjustments and no kernel involvement. Its system priority is usually uniform and is inherited from the creating process.

thr_setprio(3T)

`thr_setprio`(3T) changes the priority of the thread, specified by *tid*, within the current process to the priority specified by *newprio*. (For POSIX threads, see "pthread_setschedparam(3T)" on page 42.)

```
#include <thread.h>

int thr_setprio(thread_t tid, int newprio)
```

By default, threads are scheduled based on fixed priorities that range from zero, the least significant, to the largest integer. The *tid* will preempt lower-priority threads, and will yield to higher-priority threads.

```
thread_t tid;
int ret;
int newprio = 20;

/* suspended thread creation */
ret = thr_create(NULL, NULL, func, arg, THR_SUSPEND, &tid);

/* set the new priority of suspended child thread */
ret = thr_setprio(tid, newprio);

/* suspended child thread starts executing with new priority */
ret = thr_continue(tid);
```

Get the Thread Priority

thr_getprio(3T)

Use `thr_getprio`(3T) to get the current priority for the thread. Each thread
inherits a priority from its creator. `thr_getprio()` stores the current priority, *tid*, in
the location pointed to by *newprio*. (For POSIX threads, see
"pthread_getschedparam(3T)" on page 43.)

```
#include <thread.h>

int thr_getprio(thread_t tid, int *newprio)
```

Similar Synchronization
Functions—Mutual Exclusion Locks

- "Initialize a Mutex" on page 221
- "Destroy a Mutex" on page 223
- "Acquire a Mutex" on page 223
- "Release a Mutex" on page 223
- "Try to Acquire a Mutex" on page 224

Initialize a Mutex

mutex_init(3T)

```
#include <synch.h>    (or
#include <thread.h>)

int mutex_init(mutex_t *mp, int type, void *arg));
```

Use `mutex_init`(3T) to initialize the mutex pointed to by *mp*. The *type* can be one
of the following (note that *arg* is currently ignored). (For POSIX threads, see
"Initialize a Mutex" on page 94.)

- `USYNC_PROCESS` The mutex can be used to synchronize threads in this and other
  processes.

- USYNC_PROCESS_ROBUST The mutex can be used to *robustly* synchronize threads in this and other processes.

- USYNC_THREAD The mutex can be used to synchronize threads in this process only.

When a process dies while holding a USYNC_PROCESS lock, subsequent requestors of that lock hang. This is a problem for systems which share locks with client processes because the client processes can be abnormally killed. To avoid the problem of hanging on a lock held by a dead process, use USYNC_PROCESS_ROBUST to lock the mutex. USYNC_PROCESS_ROBUST adds two capabilities:

- In the case of process death, all owned locks held by that process are unlocked.

- The next requestor for any of the locks owned by the dead process receives the lock, but with an error return indicating that the previous owner died while holding the lock..

Mutexes can also be initialized by allocation in zeroed memory, in which case a *type* of USYNC_THREAD is assumed.

Multiple threads must not initialize the same mutex simultaneously. A mutex lock must not be reinitialized while other threads might be using it.

Mutexes With Intraprocess Scope

```
#include <thread.h>

mutex_t mp;
int ret;

/* to be used within this process only */
ret = mutex_init(&mp, USYNC_THREAD, 0);
```

Mutexes With Interprocess Scope

```
#include <thread.h>

mutex_t mp;
int ret;

/* to be used among all processes */
ret = mutex_init(&mp, USYNC_PROCESS, 0);
```

Mutexes With Interprocess Scope-Robust

```
#include <thread.h>

mutex_t mp;
int ret;

/* to be used among all processes */
ret = mutex_init(&mp, USYNC_PROCESS_ROBUST, 0);
```

Destroy a Mutex

mutex_destroy(3T)

```
#include <thread.h>

int mutex_destroy (mutex_t *mp);
```

Use `mutex_destroy`(3T) to destroy any state associated with the mutex pointed to by *mp.* Note that the space for storing the mutex is not freed. (For POSIX threads, see "pthread_mutex_destroy(3T)" on page 101.)

Acquire a Mutex

mutex_lock(3T)

```
#include <thread.h>

int mutex_lock(mutex_t *mp);
```

Use `mutex_lock`(3T) to lock the mutex pointed to by *mp.* When the mutex is already locked, the calling thread blocks until the mutex becomes available (blocked threads wait on a prioritized queue). (For POSIX threads, see "pthread_mutex_lock(3T)" on page 96.)

Release a Mutex

mutex_unlock(3T)

```
#include <thread.h>

int mutex_unlock(mutex_t *mp);
```

Use `mutex_unlock`(3T) to unlock the mutex pointed to by *mp.* The mutex must be locked and the calling thread must be the one that last locked the mutex (the owner). (For POSIX threads, see "pthread_mutex_unlock(3T)" on page 98.)

Try to Acquire a Mutex

mutex_trylock(3T)

```
#include <thread.h>

int mutex_trylock(mutex_t *mp);
```

Use `mutex_trylock`(3T) to attempt to lock the mutex pointed to by *mp*. This function is a nonblocking version of `mutex_lock()`. (For POSIX threads, see "pthread_mutex_trylock(3T)" on page 99.)

Similar Synchronization Functions—Condition Variables

- "Initialize a Condition Variable" on page 224
- "Destroy a Condition Variable" on page 225
- "Wait for a Condition" on page 225
- "Wait for an Absolute Time" on page 226
- "Signal One Condition Variable" on page 226
- "Signal All Condition Variables" on page 227

Initialize a Condition Variable

cond_init(3T)

```
#include <thread.h>

int cond_init(cond_t *cv, int type, int arg);
```

Use `cond_init`(3T) to initialize the condition variable pointed to by *cv*. The *type* can be one of the following (note that *arg* is currently ignored). (For POSIX threads, see "pthread_condattr_init(3T)" on page 107.)

- `USYNC_PROCESS` The condition variable can be used to synchronize threads in this and other processes. *arg* is ignored.
- `USYNC_THREAD` The condition variable can be used to synchronize threads in this process only. *arg* is ignored.

Condition variables can also be initialized by allocation in zeroed memory, in which case a type of `USYNC_THREAD` is assumed.

Multiple threads must not initialize the same condition variable simultaneously. A condition variable must not be reinitialized while other threads might be using it.

Condition Variables With Intraprocess Scope

```
#include <thread.h>

cond_t cv;
int ret;

/* to be used within this process only */
ret = cond_init(cv, USYNC_THREAD, 0);
```

Condition Variables With Interprocess Scope

```
#include <thread.h>

cond_t cv;
int ret;

/* to be used among all processes */
ret = cond_init(&cv, USYNC_PROCESS, 0);
```

Destroy a Condition Variable

cond_destroy(3T)

```
#include <thread.h>

int cond_destroy(cond_t *cv);
```

Use `cond_destroy`(3T) to destroy state associated with the condition variable pointed to by *cv*. The space for storing the condition variable is not freed. (For POSIX threads, see "pthread_condattr_destroy(3T)" on page 108.)

Wait for a Condition

cond_wait(3T)

```
#include <thread.h>

int cond_wait(cond_t *cv, mutex_t *mp);
```

Use `cond_wait`(3T) to atomically release the mutex pointed to by *mp* and to cause the calling thread to block on the condition variable pointed to by *cv*. The blocked thread can be awakened by `cond_signal()`, `cond_broadcast()`, or when interrupted by delivery of a signal or a `fork()`. (For POSIX threads, see "pthread_cond_wait(3T)" on page 112.)

Wait for an Absolute Time

cond_timedwait(3T)

```
#include <thread.h>
```

```
int cond_timedwait(cond_t *cv, mutex_t *mp, timestruct_t abstime)
```

Use `cond_timedwait`(3T) as you would use `cond_wait()`, except that `cond_timedwait()` does not block past the time of day specified by *abstime*. (For POSIX threads, see "pthread_cond_timedwait(3T)" on page 115.)

`cond_timedwait()` always returns with the mutex locked and owned by the calling thread even when returning an error.

The `cond_timedwait()` function blocks until the condition is signaled or until the time of day specified by the last argument has passed. The timeout is specified as the time of day so the condition can be retested efficiently without recomputing the time-out value.

Signal One Condition Variable

cond_signal(3T)

```
#include <thread.h>
```

```
int cond_signal(cond_t *cv);
```

Use `cond_signal`(3T) to unblock one thread that is blocked on the condition variable pointed to by *cv*. Call this function under protection of the same mutex used with the condition variable being signaled. Otherwise, the condition could be signaled between its test and `cond_wait()`, causing an infinite wait.

Signal All Condition Variables

cond_broadcast(3T)

```
#include <thread.h>

int cond_broadcast(cond_t *cv);
```

Use `cond_broadcast`(3T) to unblock all threads that are blocked on the condition variable pointed to by *cv*. When no threads are blocked on the condition variable then `cond_broadcast()` has no effect.

Similar Synchronization Functions—Semaphores

Semaphore operations are the same in both the Solaris Operating Environment and the POSIX environment. The function name changed from `sema_` in the Solaris Operating Environment to `sem_` in pthreads.

- "Initialize a Semaphore" on page 227
- "Increment a Semaphore" on page 228
- "Block on a Semaphore Count" on page 228
- "Decrement a Semaphore Count" on page 229
- "Destroy the Semaphore State" on page 229

Initialize a Semaphore

sema_init(3T)

```
#include <thread.h>

int sema_init(sema_t *sp, unsigned int count, int type,
    void *arg);
```

Use `sema_init`(3T) to initialize the semaphore variable pointed to by *sp* by *count* amount. *type* can be one of the following (note that *arg* is currently ignored).

`USYNC_PROCESS` The semaphore can be used to synchronize threads in this process and other processes. Only one process should initialize the semaphore. *arg* is ignored.

USYNC_THREAD The semaphore can be used to synchronize threads in this process, only. *arg* is ignored.

Multiple threads must not initialize the same semaphore simultaneously. A semaphore must not be reinitialized while other threads might be using it.

Semaphores With Intraprocess Scope

```
#include <thread.h>

sema_t sp;
int ret;
int count;
count = 4;

/* to be used within this process only */
ret = sema_init(&sp, count, USYNC_THREAD, 0);
```

Semaphores With Interprocess Scope

```
#include <thread.h>

sema_t sp;
int ret;
int count;
count = 4;

/* to be used among all the processes */
ret = sema_init (&sp, count, USYNC_PROCESS, 0);
```

Increment a Semaphore

sema_post(3T)

```
#include <thread.h>
```

```
int sema_post(sema_t *sp);
```

Use sema_post(3T) to atomically increment the semaphore pointed to by *sp*. When any threads are blocked on the semaphore, one is unblocked.

Block on a Semaphore Count

sema_wait(3T)

```
#include <thread.h>
```

```
int sema_wait(sema_t *sp);
```

Use `sema_wait`(3T) to block the calling thread until the count in the semaphore
pointed to by *sp* becomes greater than zero, then atomically decrement it.

Decrement a Semaphore Count

sema_trywait(3T)

```
#include <thread.h>

int sema_trywait(sema_t *sp);
```

Use `sem_trywait`(3R) to atomically decrement the count in the semaphore pointed
to by *sp* when the count is greater than zero. This function is a nonblocking version
of `sema_wait( )`.

Destroy the Semaphore State

sema_destroy(3T)

```
#include <thread.h>

int sema_destroy(sema_t *sp);
```

Use `sema_destroy`(3T) to destroy any state associated with the semaphore pointed
to by *sp*. The space for storing the semaphore is not freed.

Synchronization Across Process Boundaries

Each of the synchronization primitives can be set up to be used across process
boundaries. This is done quite simply by ensuring that the synchronization variable
is located in a shared memory segment and by calling the appropriate `init` routine
with type set to `USYNC_PROCESS`.

If this has been done, then the operations on the synchronization variables work just
as they do when *type* is `USYNC_THREAD`.

```
mutex_init(&m, USYNC_PROCESS, 0);

rwlock_init(&rw, USYNC_PROCESS, 0);

cond_init(&cv, USYNC_PROCESS, 0);

sema_init(&s, count, USYNC_PROCESS, 0);
```

Using LWPs Between Processes

Using locks and condition variables between processes does not require using the threads library. The recommended approach is to use the threads library interfaces, but when this is not desirable, then the _lwp_mutex_* and _lwp_cond_* interfaces can be used as follows:

1. Allocate the locks and condition variables as usual in shared memory (either with shmop(2) or mmap(2)).
2. Then initialize the newly allocated objects appropriately with the USYNC_PROCESS type. Because no interface is available to perform the initialization (_lwp_mutex_init(2) and _lwp_cond_init(2) do not exist), the objects can be initialized using statically allocated and initialized dummy objects.

For example, to initialize lockp:

```
lwp_mutex_t *lwp_lockp;
lwp_mutex_t dummy_shared_mutex = SHAREDMUTEX;
 /* SHAREDMUTEX is defined in /usr/include/synch.h */
...
...
lwp_lockp = alloc_shared_lock();
*lwp_lockp = dummy_shared_mutex;
```

Similarly, for condition variables:

```
lwp_cond_t *lwp_condp;
lwp_cond_t dummy_shared_cv = SHAREDCV;
 /* SHAREDCV is defined in /usr/include/synch.h */
...
...
lwp_condp = alloc_shared_cv();
*lwp_condp = dummy_shared_cv;
```

Producer/Consumer Problem Example

Code Example 9–2 shows the producer/consumer problem with the producer and consumer in separate processes. The main routine maps zero-filled memory (that it shares with its child process) into its address space. Note that mutex_init() and cond_init() must be called because the type of the synchronization variables is USYNC_PROCESS.

A child process is created that runs the consumer. The parent runs the producer.

This example also shows the drivers for the producer and consumer. The producer_driver() simply reads characters from stdin and calls producer(). The consumer_driver() gets characters by calling consumer() and writes them to stdout.

The data structure for Code Example 9–2 is the same as that used for the solution with condition variables (see "Nested Locking With a Singly Linked List" on page 104).

CODE EXAMPLE 9–2 The Producer/Consumer Problem, Using USYNC_PROCESS

```
main() {
    int zfd;
    buffer_t *buffer;

    zfd = open(``/dev/zero'', O_RDWR);
    buffer = (buffer_t *)mmap(NULL, sizeof(buffer_t),
        PROT_READ|PROT_WRITE, MAP_SHARED, zfd, 0);
    buffer->occupied = buffer->nextin = buffer->nextout = 0;

    mutex_init(&buffer->lock, USYNC_PROCESS, 0);
    cond_init(&buffer->less, USYNC_PROCESS, 0);
    cond_init(&buffer->more, USYNC_PROCESS, 0);
    if (fork() == 0)
        consumer_driver(buffer);
    else
        producer_driver(buffer);
}

void producer_driver(buffer_t *b) {
    int item;

    while (1) {
        item = getchar();
        if (item == EOF) {
            producer(b, '\0');
            break;
        } else
            producer(b, (char)item);
    }
}

void consumer_driver(buffer_t *b) {
    char item;

    while (1) {
        if ((item = consumer(b)) == '\0')
            break;
        putchar(item);
    }
}
```

A child process is created to run the consumer; the parent runs the producer.

Special Issues for fork() and Solaris Threads

Solaris threads and POSIX threads define the behavior of `fork()` differently. See "Process Creation—exec(2)and exit(2) Issues" on page 148 for a thorough discussion of `fork()` issues.

Solaris `libthread` supports both `fork()` and `fork1()`. The `fork()` call has "fork-all" semantics—it duplicates everything in the process, including threads and LWPs, creating a true clone of the parent. The `fork1()` call creates a clone that has only one thread; the process state and address space are duplicated, but only the calling thread is cloned.

POSIX `libpthread` supports only `fork()`, which has the same semantics as `fork1()` in Solaris threads.

Whether `fork()` has "fork-all" semantics or "fork-one" semantics is dependent on which library is used. Linking with −`lthread` assigns "fork-all" semantics to `fork()`, while linking with −`lpthread` assigns "fork-one" semantics to `fork()`.

See "Linking With libthread or libpthread" on page 177 for more details.

Programming Guidelines

This chapter gives some pointers on programming with threads. Most pointers apply to both Solaris and POSIX threads, but where functionality differs, it is noted. Changing from single-threaded thinking to multithreaded thinking is emphasized in this chapter.

Rethinking Global Variables

Historically, most code has been designed for single-threaded programs. This is especially true for most of the library routines called from C programs. The following implicit assumptions were made for single-threaded code:

- When you write into a global variable and then, a moment later, read from it, what you read is exactly what you just wrote.

- This is also true for nonglobal, static storage.

- You do not need synchronization because there is nothing to synchronize with.

The next few examples discuss some of the problems that arise in multithreaded programs because of these assumptions, and how you can deal with them.

Traditional, single-threaded C and UNIX have a convention for handling errors detected in system calls. System calls can return anything as a functional value (for example, `write()` returns the number of bytes that were transferred). However, the value -1 is reserved to indicate that something went wrong. So, when a system call returns -1, you know that it failed.

CODE EXAMPLE 10–1   Global Variables and *errno*

```
extern int errno;
...
if (write(file_desc, buffer, size) == -1) {
    /* the system call failed */
    fprintf(stderr, ``something went wrong, ``
        ``error code = %d\n'', errno);
    exit(1);
}
...
```

Rather than return the actual error code (which could be confused with normal return values), the error code is placed into the global variable errno. When the system call fails, you can look in errno to find out what went wrong.

Now consider what happens in a multithreaded environment when two threads fail at about the same time, but with different errors. Both expect to find their error codes in errno, but one copy of errno cannot hold both values. This global variable approach simply does not work for multithreaded programs.

Threads solves this problem through a conceptually new storage class—thread-specific data. This storage is similar to global storage in that it can be accessed from any procedure in which a thread might be running. However, it is private to the thread—when two threads refer to the thread-specific data location of the same name, they are referring to two different areas of storage.

So, when using threads, each reference to errno is thread specific because each thread has a private copy of errno. This is achieved in this implementation by making errno a macro that expands to a function call.

Providing for Static Local Variables

Code Example 10–2 shows a problem similar to the errno problem, but involving static storage instead of global storage. The function gethostbyname(3N) is called with the computer name as its argument. The return value is a pointer to a structure containing the required information for contacting the computer through network communications.

CODE EXAMPLE 10–2 The `gethostbyname()` Problem

```
struct hostent *gethostbyname(char *name) {
    static struct hostent result;
        /* Lookup name in hosts database */
        /* Put answer in result */
    return(&result);
}
```

Returning a pointer to a local variable is generally not a good idea, although it works in this case because the variable is static. However, when two threads call this variable at once with different computer names, the use of static storage conflicts.

Thread-specific data could be used as a replacement for static storage, as in the `errno` problem, but this involves dynamic allocation of storage and adds to the expense of the call.

A better way to handle this kind of problem is to make the caller of `gethostbyname()` supply the storage for the result of the call. This is done by having the caller supply an additional argument, an output argument, to the routine. This requires a new interface to `gethostbyname()`.

This technique is used in threads to fix many of these problems. In most cases, the name of the new interface is the old name with "`_r`" appended, as in `gethostbyname_r(3N)`.

Synchronizing Threads

The threads in an application must cooperate and synchronize when sharing the data and the resources of the process.

A problem arises when multiple threads call something that manipulates an object. In a single-threaded world, synchronizing access to such objects is not a problem, but as Code Example 10–3 illustrates, this is a concern with multithreaded code. (Note that the `printf(3S)` function is safe to call for a multithreaded program; this example illustrates what could happen if `printf()` were not safe.)

CODE EXAMPLE 10–3 The `printf()` Problem

```
/* thread 1: */
    printf("go to statement reached");

/* thread 2: */
    printf("hello world");

printed on display:
    go to hello
```

Single-Threaded Strategy

One strategy is to have a single, application-wide mutex lock that is acquired whenever any thread in the application is running and is released before it must block. Since only one thread can be accessing shared data at any one time, each thread has a consistent view of memory.

Because this is effectively a single-threaded program, very little is gained by this strategy.

Reentrance

A better approach is to take advantage of the principles of modularity and data encapsulation. A reentrant function is one that behaves correctly if it is called simultaneously by several threads. Writing a reentrant function is a matter of understanding just what *behaves correctly* means for this particular function.

Functions that are callable by several threads must be made reentrant. This might require changes to the function interface or to the implementation.

Functions that access global state, like memory or files, have reentrance problems. These functions need to protect their use of global state with the appropriate synchronization mechanisms provided by threads.

The two basic strategies for making functions in modules reentrant are code locking and data locking.

Code Locking

Code locking is done at the function call level and guarantees that a function executes entirely under the protection of a lock. The assumption is that all access to data is done through functions. Functions that share data should execute under the same lock.

Some parallel programming languages provide a construct called a monitor that implicitly does code locking for functions that are defined within the scope of the monitor. A monitor can also be implemented by a mutex lock.

Functions under the protection of the same mutex lock or within the same monitor are guaranteed to execute atomically with respect to each other.

Data Locking

Data locking guarantees that access to a collection of data is maintained consistently. For data locking, the concept of locking code is still there, but code locking is around references to shared (global) data, only. For a mutual exclusion locking protocol, only one thread can be in the critical section for each collection of data.

Alternatively, in a multiple readers, single writer protocol, several readers can be allowed for each collection of data or one writer. Multiple threads can execute in a single module when they operate on different data collections and do not conflict on a single collection for the multiple readers, single writer protocol. So, data locking typically allows more concurrency than does code locking. (Note that Solaris threads has "Readers/Writer Lock" functionality built in.)

What strategy should you use when using locks (whether implemented with mutexes, condition variables, or semaphores) in a program? Should you try to achieve maximum parallelism by locking only when necessary and unlocking as soon as possible (fine-grained locking)? Or should you hold locks for long periods to minimize the overhead of taking and releasing them (coarse-grained locking)?

The granularity of the lock depends on the amount of data it protects. A very coarse-grained lock might be a single lock to protect all data. Dividing how the data is protected by the appropriate number of locks is very important. Too fine a grain of locking can degrade performance. The overhead associated with acquiring and releasing locks can become significant when there are too many locks.

The common wisdom is to start with a coarse-grained approach, identify bottlenecks, and add finer-grained locking where necessary to alleviate the bottlenecks. This is reasonably sound advice, but use your own judgment about finding the balance between maximizing parallelism and minimizing lock overhead.

Invariants

For both code locking and data locking, *invariants* are important to control locking complexity. An invariant is a condition or relation that is always true.

The definition is modified somewhat for concurrent execution: an invariant is a condition or relation that is true when the associated lock is being set. Once the lock is set, the invariant can be false. However, the code holding the lock must reestablish the invariant before releasing the lock.

An invariant can also be a condition or relation that is true when a lock is being set. Condition variables can be thought of as having an invariant that is the condition.

CODE EXAMPLE 10–4   Testing the Invariant With assert(3X)

```
mutex_lock(&lock);
while((condition)==FALSE)
    cond_wait(&cv,&lock);
assert((condition)==TRUE);
   .
   .
   .
mutex_unlock(&lock);
```

The `assert()` statement is testing the invariant. The `cond_wait()` function does not preserve the invariant, which is why the invariant must be reevaluated when the thread returns.

Another example is a module that manages a doubly linked list of elements. For each item on the list a good invariant is the forward pointer of the previous item on the list that should also point to the same thing as the backward pointer of the forward item.

Assume this module uses code-based locking and therefore is protected by a single global mutex lock. When an item is deleted or added the mutex lock is acquired, the correct manipulation of the pointers is made, and the mutex lock is released. Obviously, at some point in the manipulation of the pointers the invariant is false, but the invariant is reestablished before the mutex lock is released.

Avoiding Deadlock

Deadlock is a permanent blocking of a set of threads that are competing for a set of resources. Just because some thread can make progress does not mean that there is not a deadlock somewhere else.

The most common error causing deadlock is *self deadlock* or *recursive deadlock*: a thread tries to acquire a lock it is already holding. Recursive deadlock is very easy to program by mistake.

For example, if a code monitor has every module function grabbing the mutex lock for the duration of the call, then any call between the functions within the module protected by the mutex lock immediately deadlocks. If a function calls some code outside the module which, through some circuitous path, calls back into any method protected by the same mutex lock, then it will deadlock too.

The solution for this kind of deadlock is to avoid calling functions outside the module when you don't know whether they will call back into the module without reestablishing invariants and dropping all module locks before making the call. Of course, after the call completes and the locks are reacquired, the state must be verified to be sure the intended operation is still valid.

An example of another kind of deadlock is when two threads, thread 1 and thread 2, each acquires a mutex lock, A and B, respectively. Suppose that thread 1 tries to acquire mutex lock B and thread 2 tries to acquire mutex lock A. Thread 1 cannot proceed and it is blocked waiting for mutex lock B. Thread 2 cannot proceed and it is blocked waiting for mutex lock A. Nothing can change, so this is a permanent blocking of the threads, and a deadlock.

This kind of deadlock is avoided by establishing an order in which locks are acquired (a *lock hierarchy*). When all threads always acquire locks in the specified order, this deadlock is avoided.

Adhering to a strict order of lock acquisition is not always optimal. When thread 2 has many assumptions about the state of the module while holding mutex lock B, giving up mutex lock B to acquire mutex lock A and then reacquiring mutex lock B

in order would cause it to discard its assumptions and reevaluate the state of the module.

The blocking synchronization primitives usually have variants that attempt to get a lock and fail if they cannot, such as `mutex_trylock()`. This allows threads to violate the lock hierarchy when there is no contention. When there is contention, the held locks must usually be discarded and the locks reacquired in order.

Deadlocks Related to Scheduling

Because there is no guaranteed order in which locks are acquired, a problem in threaded programs is that a particular thread never acquires a lock, even though it seems that it should.

This usually happens when the thread that holds the lock releases it, lets a small amount of time pass, and then reacquires it. Because the lock was released, it might seem that the other thread should acquire the lock. But, because nothing blocks the thread holding the lock, it continues to run from the time it releases the lock until it reacquires the lock, and so no other thread is run.

You can usually solve this type of problem by calling `thr_yield(3T)` just before the call to reacquire the lock. This allows other threads to run and to acquire the lock.

Because the time-slice requirements of applications are so variable, the threads library does not impose any. Use calls to `thr_yield()` to make threads share time as you require.

Locking Guidelines

Here are some simple guidelines for locking.

- Try not to hold locks across long operations like I/O where performance can be adversely affected.
- Don't hold locks when calling a function that is outside the module and that might reenter the module.
- In general, start with a coarse-grained approach, identify bottlenecks, and add finer-grained locking where necessary to alleviate the bottlenecks. Most locks are held for short amounts of time and contention is rare, so fix only those locks that have measured contention.
- When using multiple locks, avoid deadlocks by making sure that all threads acquire the locks in the same order.

Following Some Basic Guidelines

- Know what you are importing and whether it is safe.

  A threaded program cannot arbitrarily enter nonthreaded code.

- Threaded code can safely refer to unsafe code only from the initial thread.

  This ensures that the static storage associated with the initial thread is used only by that thread.

- Sun-supplied libraries are defined to be *safe* unless explicitly documented as unsafe.

  If a reference manual entry does not say whether a function is MT-Safe, it is safe. All MT-unsafe functions are identified explicitly in the manual page.

- Use compilation flags to manage binary incompatible source changes. (See Chapter 7, Compiling and Debugging, for complete instructions.)

  - `-D_REENTRANT` enables multithreading with the `-lthread` library.

  - `-D_POSIX_C_SOURCE` with `-lpthread` gives POSIX threads behavior.

  - `-D_POSIX_PTHREADS_SEMANTICS` with `-lthread` gives both Solaris threads and pthreads interfaces with a preference given to the POSIX interfaces when the two interfaces conflict.

- When making a library safe for multithreaded use, do not thread global process operations.

  Do not change global operations (or actions with global side effects) to behave in a threaded manner. For example, if file I/O is changed to per-thread operation, threads cannot cooperate in accessing files.

  For thread-specific behavior, or *thread cognizant* behavior, use thread facilities. For example, when the termination of `main()` should terminate only the thread that is exiting `main()`, the end of `main()` should be:

  ```
  thr_exit();
    /*NOTREACHED*/
  ```

Creating and Using Threads

The threads packages will cache the threads data structure, stacks, and LWPs so that the repetitive creation of unbound threads can be inexpensive.

Unbound thread creation has considerable overhead when compared to process creation or even to bound thread creation. In fact, the overhead is similar to unbound thread synchronization when you include the context switches to stop one thread and start another.

So, creating and destroying threads as they are required is usually better than attempting to manage a pool of threads that wait for independent work.

A good example of this is an RPC server that creates a thread for each request and destroys it when the reply is delivered, instead of trying to maintain a pool of threads to service requests.

While thread creation has less overhead compared to that of process creation, it is not efficient when compared to the cost of a few instructions. Create threads for processing that lasts at least a couple of thousand machine instructions.

Lightweight Processes

Figure 10–1 illustrates the relationship between LWPs and the user and kernel levels.
Figure 10–1   Multithreading Levels and Relationships

The user-level threads library, with help from the programmer and the operating environment, ensures that the number of LWPs available is adequate for the currently active user-level threads. However, there is no one-to-one mapping between user threads and LWPs, and user-level threads can freely migrate from one LWP to another.

With Solaris threads, a programmer can tell the threads library how many threads should be "running" at the same time.

For example, if the programmer says that up to three threads should run at the same time, then at least three LWPs should be available. If there are three available processors, the threads run in parallel. If there is only one processor, then the operating environment multiplexes the three LWPs on that one processor. If all the LWPs block, the threads library adds another LWP to the pool.

When a user thread blocks due to synchronization, its LWP transfers to another runnable thread. This transfer is done with a coroutine linkage and not with a system call.

The operating environment decides which LWP should run on which processor and when. It has no knowledge about what user threads are or how many are active in each process.

The kernel schedules LWPs onto CPU resources according to their scheduling classes and priorities. The threads library schedules threads on the process pool of LWPs in much the same way.

Each LWP is independently dispatched by the kernel, performs independent system calls, incurs independent page faults, and runs in parallel on a multiprocessor system.

An LWP has some capabilities that are not exported directly to threads, such as a special scheduling class.

Unbound Threads

The library invokes LWPs as needed and assigns them to execute runnable threads. The LWP assumes the state of the thread and executes its instructions. If the thread becomes blocked on a synchronization mechanism, or if another thread should be run, the thread state is saved in process memory and the threads library assigns another thread to the LWP to run.

Bound Threads

Sometimes having more threads than LWPs, as can happen with unbound threads, is a disadvantage.

For example, a parallel array computation divides the rows of its arrays among different threads. If there is one LWP for each processor, but multiple threads for each LWP, each processor spends time switching between threads. In this case, it is better to have one thread for each LWP, divide the rows among a smaller number of threads, and reduce the number of thread switches.

A mixture of threads that are permanently bound to LWPs and unbound threads is also appropriate for some applications.

An example of this is a realtime application that has some threads with system-wide priority and realtime scheduling, and other threads that attend to background computations. Another example is a window system with unbound threads for most operations and a mouse serviced by a high-priority, bound, realtime thread.

When a user-level thread issues a system call, the LWP running the thread calls into the kernel and remains attached to the thread at least until the system call completes.

Bound threads require more overhead than unbound threads. Because bound threads can change the attributes of the underlying LWP, the LWPs are not cached when the bound threads exit. Instead, the operating environment provides a new LWP when a bound thread is created and destroys it when the bound thread exits.

Use bound threads only when a thread needs resources that are available only through the underlying LWP, such as a virtual time interval timer or an alternate stack, or when the thread must be visible to the kernel to be scheduled with respect to all other active threads in the system, as in realtime scheduling.

Use unbound threads even when you expect all threads to be active simultaneously. This enables Solaris threads to cache LWP and thread resources efficiently so that thread creation and destruction are fast. Use `thr_setconcurrency(3T)` to tell Solaris threads how many threads you expect to be simultaneously active.

Thread Concurrency (Solaris Threads Only)

By default, Solaris threads attempts to adjust the system execution resources (LWPs) used to run unbound threads to match the real number of active threads. While the Solaris threads package cannot make perfect decisions, it at least ensures that the process continues to make progress.

When you have some idea of the number of unbound threads that should be simultaneously active (executing code or system calls), tell the library through `thr_setconcurrency`(3T).

For example:

- A database server that has a thread for each user should tell Solaris threads the expected number of simultaneously active users.

- A window server that has one thread for each client should tell Solaris threads the expected number of simultaneously active clients.

- A file copy program that has one reader thread and one writer thread should tell Solaris threads that the desired concurrency level is two.

Alternatively, the concurrency level can be incremented by one through the `THR_NEW_LWP` flag as each thread is created.

Include unbound threads blocked on interprocess (`USYNC_PROCESS`) synchronization variables as active when you compute thread concurrency. Exclude

bound threads—they do not require concurrency support from Solaris threads because they are equivalent to LWPs.

Efficiency

A new thread is created with `thr_create(3T)` in less time than an existing thread can be restarted. This means that it is more efficient to create a new thread when one is needed and have it call `thr_exit(3T)` when it has completed its task than it would be to stockpile an idle thread and restart it.

Thread Creation Guidelines

Here are some simple guidelines for using threads.

- Use threads for independent activities that must do a meaningful amount of work.

- Use Solaris threads to take advantage of CPU concurrency.

- Use bound threads only when absolutely necessary, that is, when some facility of the underlying LWP is required.

Working With Multiprocessors

Multithreading lets you take advantage of multiprocessors, primarily through parallelism and scalability. Programmers should be aware of the differences between the memory models of a multiprocessor and a uniprocessor.

Memory consistency is directly interrelated to the processor interrogating memory. For uniprocessors, memory is obviously consistent because there is only one processor viewing memory.

To improve multiprocessor performance, memory consistency is relaxed. You cannot always assume that changes made to memory by one processor are immediately reflected in the other processors' views of that memory.

You can avoid this complexity by using synchronization variables when you use shared or global variables.

Barrier synchronization is sometimes an efficient way to control parallelism on multiprocessors. An example of barriers can be found in Appendix B, Solaris Threads Example: barrier.c.

Another multiprocessor issue is efficient synchronization when threads must wait until all have reached a common point in their execution.

> **Note -** The issues discussed here are not important when the threads synchronization primitives are always used to access shared memory locations.

The Underlying Architecture

When threads synchronize access to shared storage locations using the threads synchronization routines, the effect of running a program on a shared-memory multiprocessor is identical to the effect of running the program on a uniprocessor.

However, in many situations a programmer might be tempted to take advantage of the multiprocessor and use "tricks" to avoid the synchronization routines. As Code Example 10–5 and Code Example 10–6 show, such tricks can be dangerous.

Understanding the memory models supported by common multiprocessor architectures helps to understand the dangers.

The major multiprocessor components are:

- The processors themselves
- Store buffers, which connect the processors to their caches
- *Caches*, which hold the contents of recently accessed or modified storage locations
- memory, which is the primary storage (and is shared by all processors).

In the simple traditional model, the multiprocessor behaves as if the processors are connected directly to memory: when one processor stores into a location and another immediately loads from the same location, the second processor loads what was stored by the first.

Caches can be used to speed the average memory access, and the desired semantics can be achieved when the caches are kept consistent with one another.

A problem with this simple approach is that the processor must often be delayed to make certain that the desired semantics are achieved. Many modern multiprocessors use various techniques to prevent such delays, which, unfortunately, change the semantics of the memory model.

Two of these techniques and their effects are explained in the next two examples.

"Shared-Memory" Multiprocessors

Consider the purported solution to the producer/consumer problem shown in Code Example 10–5.

Although this program works on current SPARC-based multiprocessors, it assumes that all multiprocessors have strongly ordered memory. This program is therefore not portable.

CODE EXAMPLE 10–5 The Producer/Consumer Problem—Shared Memory Multiprocessors

```
                    char buffer[BSIZE];
                    unsigned int in = 0;
                    unsigned int out = 0;

void                            char
producer(char item) {             consumer(void) {
                                   char item;
    do                              
        ;/* nothing */              do
    while                               ;/* nothing */
        (in - out == BSIZE);        while
                                        (in - out == 0);
    buffer[in%BSIZE] = item;        item = buffer[out%BSIZE];
    in++;                           out++;
}                               }
```

When this program has exactly one producer and exactly one consumer and is run on a shared-memory multiprocessor, it appears to be correct. The difference between *in* and *out* is the number of items in the buffer.

The producer waits (by repeatedly computing this difference) until there is room for a new item, and the consumer waits until there is an item in the buffer.

For memory that is *strongly ordered* (for instance, a modification to memory on one processor is immediately available to the other processors), this solution is correct (it is correct even taking into account that *in* and *out* will eventually overflow, as long as BSIZE is less than the largest integer that can be represented in a word).

Shared-memory multiprocessors do not necessarily have strongly ordered memory. A change to memory by one processor is not necessarily available immediately to the other processors. When two changes to different memory locations are made by one processor, the other processors do not necessarily detect the changes in the order in which they were made because changes to memory do not happen immediately.

First the changes are stored in *store buffers* that are not visible to the cache.

The processor checks these store buffers to ensure that a program has a consistent view, but because store buffers are not visible to other processors, a write by one processor does not become visible until it is written to cache.

The synchronization primitives (see Chapter 4, Programming With Synchronization Objects) use special instructions that flush the store buffers to cache. So, using locks around your shared data ensures memory consistency.

When memory ordering is very relaxed, Code Example 10–5 has a problem because the consumer might see that *in* has been incremented by the producer before it sees the change to the corresponding buffer slot.

This is called *weak ordering* because stores made by one processor can appear to happen out of order by another processor (memory, however, is always consistent from the same processor). To fix this, the code should use mutexes to flush the cache.

The trend is toward relaxing memory order. Because of this, programmers are becoming increasingly careful to use locks around all global or shared data.

As demonstrated by Code Example 10–5 and Code Example 10–6, locking is essential.

Peterson's Algorithm

The code in Code Example 10–6 is an implementation of Peterson's Algorithm, which handles mutual exclusion between two threads. This code tries to guarantee that there is never more than one thread in the critical section and that, when a thread calls `mut_excl()`, it enters the critical section sometime "*soon.*"

An assumption here is that a thread exits fairly quickly after entering the critical section.

CODE EXAMPLE 10–6   Mutual Exclusion for Two Threads?

```
void mut_excl(int me /* 0 or 1 */) {
    static int loser;
    static int interested[2] = {0, 0};
    int other; /* local variable */

    other = 1 - me;
    interested[me] = 1;
    loser = me;
    while (loser == me && interested[other])
        ;

    /* critical section */
    interested[me] = 0;
}
```

This algorithm works some of the time when it is assumed that the multiprocessor has strongly ordered memory.

Some multiprocessors, including some SPARC-based multiprocessors, have store buffers. When a thread issues a store instruction, the data is put into a store buffer. The buffer contents are eventually sent to the cache, but not necessarily right away. (Note that the caches on each of the processors maintain a consistent view of memory, but modified data does not reach the cache right away.)

When multiple memory locations are stored into, the changes reach the cache (and memory) in the correct order, but possibly after a delay. SPARC-based multiprocessors with this property are said to have total store order (TSO).

When one processor stores into location A and then loads from location B, and another processor stores into location B and loads from location A, the expectation is that either the first processor fetches the newly modified value in location B or the second processor fetches the newly modified value in location A, or both. However, the case in which both processors load the old values simply cannot happen.

Moreover, with the delays caused by load and store buffers, the "impossible case" can happen.

What could happen with Peterson's algorithm is that two threads running on separate processors each stores into its own slot of the particular array and then loads from the other slot. They both read the old values (0), assume that the other party is not present, and both enter the critical section. (Note that this is the sort of problem that might not occur when you test a program, but only much later.)

This problem is avoided when you use the threads synchronization primitives, whose implementations issue special instructions to force the writing of the store buffers to the cache.

Parallelizing a Loop on a Shared-Memory Parallel Computer

In many applications, and especially numerical applications, while part of the algorithm can be parallelized, other parts are inherently sequential, as shown in the following:

```
Thread₁                              Thread₂ through Threadₙ

while(many_iterations) {              while(many_iterations) {

   sequential_computation
   --- Barrier ---                        --- Barrier ---
   parallel_computation                   parallel_computation
}                                     }
```

For example, you might produce a set of matrixes with a strictly linear computation, then perform operations on the matrixes using a parallel algorithm, then use the results of these operations to produce another set of matrixes, then operate on them in parallel, and so on.

The nature of the parallel algorithms for such a computation is that little synchronization is required during the computation, but synchronization of all the threads employed is required to ensure that the sequential computation is finished before the parallel computation begins.

The barrier forces all the threads that are doing the parallel computation to wait until all threads involved have reached the barrier. When they've reached the barrier, they are released and begin computing together.

Summary

This guide has covered a wide variety of important threads programming issues. Look in Appendix A, Sample Application—Multithreaded grep, for a pthreads program example that uses many of the features and styles that have been discussed. Look in Appendix B, Solaris Threads Example, for a program example that uses Solaris threads.

Further Reading

For more in-depth information about multithreading, see the following book:

- *Programming with Threads* by Steve Kleiman, Devang Shah, and Bart Smaalders (Prentice-Hall, published in 1995)

Sample Application—Multithreaded `grep`

Description of `tgrep`

The `tgrep` sample program is a multithreaded version of find(1) combined with grep(1). `tgrep` supports all but the –w (word search) options of the normal `grep`, and a few exclusively available options.

By default, the `tgrep` searches are like the following command:

```
find . -exec grep [ options ] pattern {} \;
```

For large directory hierarchies, `tgrep` gets results more quickly than the `find` command, depending on the number of processors available. On uniprocessor machines it is about twice as fast, and on four processor machines it is about four times as fast.

The –e option changes the way `tgrep` interprets the pattern string. Ordinarily (without the –e option) `tgrep` uses a literal string match. With the –e option, `tgrep` uses an MT-Safe public domain version of a regular expression handler. The regular expression method is slower.

The –B option tells `tgrep` to use the value of the environment variable called `TGLIMIT` to limit the number of threads it will use during a search. This option has no affect if `TGLIMIT` is not set. Because `tgrep` can use a lot of system resources, this is a way to run it politely on a timesharing system.

Solaris Threads Example: `barrier.c`

The `barrier.c` program demonstrates an implementation of a barrier for Solaris threads. (See "Parallelizing a Loop on a Shared-Memory Parallel Computer" on page 248 for a definition of barriers.)

CODE EXAMPLE B–1   Solaris Threads Example: `barrier.c`

```
#define _REENTRANT

/* Include Files        */

#include <thread.h>
#include <errno.h>

/* Constants & Macros   *

/* Data Declarations    */

typedef struct {
    int     maxcnt;     /* maximum number of runners */
    struct _sb {
        cond_t  wait_cv;   /* cv for waiters at barrier */
        mutex_t wait_lk;   /* mutex for waiters at barrier */
        int     runners;   /* number of running threads */
    } sb[2];
    struct _sb   *sbp;    /* current sub-barrier */
} barrier_t;

/*
 * barrier_init - initialize a barrier variable.
 *
 */

int
barrier_init( barrier_t *bp, int count, int type, void *arg ) {
    int n;
```

```
        int i;

        if (count < 1)
            return(EINVAL);

        bp->maxcnt = count;
        bp->sbp = &bp->sb[0];
